23 **Abstract**  
24  
25 What animals eat modulates their microbiome and is fundamental to their health.  
26 Microbiomes can improve hosts' ability to cope with environmental stressors, including  
27 increased temperatures and altered food quantity and quality associated with climate change.  
28 Using a multifactorial experimental design, we tested whether three diets with increasing  
29 amounts of protein, fat, and components of animal origin (designated low-, intermediate-, and  
30 high-quality), two rearing temperatures (18 °C or 24.5 °C), and exposure or not to a heat wave  
31 (28 °C for 48 h) shaped the gut bacterial community of amphibian larvae (*Rana temporaria*).  
32 We then examined how the treatments, associated shifts in gut bacterial communities, and  
33 predicted metabolic pathways related to larvae nutrient assimilation (isotopic signatures),  
34 health (body condition and developmental rate), and escape behavior. Larvae maintained their  
35 body condition and developed faster at 24.5 °C, with higher diet quality (i.e., reduced  
36 herbivory) further accelerating development at this temperature. The intermediate-quality diet  
37 reduced the ability of larvae to react to an aversive stimulus at 24.5 °C, but this effect did not  
38 occur in larvae exposed to the heat wave. The heat wave may have triggered an increase in the  
39 abundance of *Klebsiella*, together with an increase in the myo-inositol degradation pathway,  
40 which influences cell membrane fluidity and signaling and may increase attention levels.  
41 Similar outcomes in host performance under most experimental conditions highlight the  
42 potential plasticity of the bacterial community and the presence of alternative enterotypes  
43 with functionally redundant metabolic capacities compatible with host health.  
44  
45 *Key-words:* Food quality, thermal stress, bacteria, escape behavior, developmental plasticity,  
46 behavioral plasticity, gut-brain-axis, *Rana temporaria*

48

49 **Introduction**

50

51 What animals eat shapes their available energy, growth, and development, ultimately  
52 affecting their likelihood of survival (e.g., Kupferberg, 1997; Wang et al., 2015; Llobat and  
53 Marín-García, 2022). Beyond its nutritional value, food intake also influences the microbiome  
54 - the diverse community of microorganisms (Archaea, Bacteria, Fungi, Protists, Viruses), their  
55 metabolites, and interactions (Berg et al., 2020) - that inhabit animal guts (Tuddenham and  
56 Sears, 2015) and contribute critically to nutrient assimilation and host health (McFall-Ngai et  
57 al., 2013). Animals and their mutualistic or commensal microbial partners have likely been  
58 co-evolving since the origin of the animal kingdom (McFall-Ngai et al., 2013). This long-  
59 standing association expanded the metabolic potential of animals, enabling the use of  
60 otherwise inaccessible food resources and tightly linking host and microbiome genomes  
61 (McFall-Ngai et al., 2013). The gut microbiome supports digestion and the assimilation of end  
62 products by host cells (Perry et al., 2020) and may further influence the host's ability to cope  
63 with environmental stress by regulating specific metabolic pathways (Fontaine and Kohl,  
64 2023). Because microbiomes respond more rapidly to changing conditions than host genomes,  
65 they act as key mediators of animal resilience to environmental stress.

66 Human activities and resulting climate change have created a world in which wildlife  
67 faces multiple stressors that compromise individual health, drive population declines, and can  
68 ultimately trigger species extinctions (Ruddiman, 2013; McCallum, 2015). Climate change  
69 encompasses not only increasing mean temperatures but also transient temperature extremes,  
70 altered precipitation patterns, droughts, and shifts in food webs, food quality, and food  
71 availability (IPCC, 2023; Hardison and Eliason, 2024). Animals are exposed to both  
72 prolonged elevated temperatures and short-term heat waves, with responses varying according  
73 to the intensity and duration of thermal stress (Carreira et al., 2016). The increasing  
74 occurrence of heat waves in Europe, Asia, and Australia (IPCC, 2023) highlights their likely  
75 importance for the fate of species under climate change.

76 Emerging evidence suggests that gut microbes play a role in mediating heat tolerance in  
77 ectotherms. Conversely, impoverished microbiomes may reduce ectotherm tolerance to  
78 thermal extremes (Fontaine et al., 2022; Fontaine and Kohl, 2023). Shifts in microbiome  
79 composition can modify host thermal resilience by influencing metabolic pathways, oxidative  
80 stress resistance, and energy balance. For example, pathways linked to amino acid metabolism  
81 - often enriched in hosts with diverse microbiomes - may allow hosts to use bacteria-derived  
82 amino acids as additional energy sources during thermal stress (Fontaine and Kohl, 2023).

83 Even species with comparatively high warming tolerance may experience costs at higher  
84 temperatures (Duarte et al., 2012). Temperature changes can alter predator-prey dynamics  
85 (Seifert et al., 2014), affect key physiological processes, and influence nutrient assimilation  
86 (Croll and Watts, 2004). This can lead to shifts in foraging behavior and food preferences  
87 (Carreira et al., 2016) and ultimately influence food webs (Seifert et al., 2014). For example,  
88 omnivorous amphibian larvae increase their consumption of plant material relative to animal  
89 food at higher temperatures, improving growth and performance (Carreira et al., 2016). In  
90 crayfish, increased temperatures reduce protein absorption but increase soluble carbohydrate  
91 absorption (Croll and Watts, 2004), helping explain reduced consumption of animal-based

92 foods at high temperatures. Thus, diet preferences respond to temperature (Behrens and  
93 Lafferty, 2007; Devries and Appel, 2014; Carreira et al., 2016), while the microbiome  
94 responds to diet (Tuddernham and Sears, 2015) and can itself influence food intake and  
95 behavior (Miri et al., 2023). Food quality and availability, as well as the abundance of key  
96 microbial groups, are influenced by the same environmental stressors that affect host survival  
97 and recruitment, making these interactions important determinants of species success or  
98 failure (e.g., Manning and Sullivan, 2021; Yan et al., 2024; Videvall et al., 2023). Yet, the  
99 combined effects of diet and temperature on the microbiome remain poorly understood  
100 (Hardison and Eliason, 2024).

101 Behavioral changes influenced by the microbiome extend beyond shifts in foraging  
102 behavior (Wong et al., 2015; Miri et al., 2023). Gut microbes produce and regulate numerous  
103 neuroactive substances - hormones, neuropeptides, neurotransmitters, and many metabolites  
104 that affect host metabolic pathways (Lynch & Hsiao, 2019). These microbial compounds  
105 influence neuronal signaling and neural development (Bercik et al., 2012) and include  
106 enzymes that synthesize key neuroactive molecules involved in behavioral regulation (Dinan  
107 et al., 2015; Chen et al., 2013). This modulation is coordinated through the gut-brain axis - a  
108 bidirectional network operating through neural (especially via the vagus nerve), endocrine,  
109 and immune pathways (Miri et al., 2023; Silva et al., 2020). Short-chain fatty acids (SCFAs)  
110 exemplify influential microbial metabolites that maintain gut integrity, modulate immune and  
111 endocrine function, and cross the blood-brain barrier to affect neurotransmission,  
112 neurotrophic factors, and microglial activity (Silva et al., 2020).

113 Much research on microbiome-driven behavior has focused on humans or mice as model  
114 organisms (Sampson and Mazmanian, 2015), yet understanding the microbiome's role in  
115 wildlife evolution and survival is urgently needed (Hird, 2017). In house sparrows,  
116 microbiome diversity correlates with exploratory behavior, which in turn promotes greater  
117 microbiome diversity (Florkowski and Yorzinski, 2023). The microbiome also influences  
118 mate choice and social behavior, with implications for individual fitness and evolutionary  
119 success (Sharon et al., 2010; Archie and Theis, 2011). Studies on microbiome-ectotherm  
120 interactions are especially important given the sensitivity of ectotherms to climate change and  
121 the potential role of their microbiome in mitigating associated stressors (Fontaine and Kohl,  
122 2023).

123 Among ectotherms, amphibians are particularly vulnerable to climate change and other  
124 stressors (Collins and Storfer, 2003; Hayes et al., 2010; Luedtke et al., 2023), making them  
125 the most threatened vertebrate group globally (Wake & Vredenburg, 2008; Borzée et al.,  
126 2025). They are therefore valuable model organisms for studying interactions among climate  
127 change, diet, microbiome, and behavior. Amphibian diet shapes larval growth and  
128 development (Kupferberg, 1997; Carreira et al., 2016; Ruthsatz et al., 2019), while the  
129 microbiome affects larval thermal stress tolerance (Fontaine and Kohl, 2023). Altered  
130 foraging behavior may reduce thermal stress impacts (Carreira et al., 2016), yet amphibian  
131 larvae often exhibit lower thermal tolerance than their predators, potentially increasing their  
132 vulnerability to predation (Bastiani, 2023). For instance, larvae of the treefrog *Pithecopus*  
133 *rusticus* showed reduced thermal acclimation capacity and thermal tolerance compared to a  
134 co-occurring dragonfly predator, losing locomotor capacity at temperatures at which predators

135 remained active (Bastiani, 2023). Because predation is a major source of mortality during  
136 larval development (McDiarmid and Altig, 1999; Wells, 2019), the ability to avoid predators  
137 is essential for survival. Predator avoidance behavior depends on both immobility in response  
138 to predator cues (Relyea, 2001; Preston and Forstner, 2015; Eterovick et al., 2020) and rapid  
139 escape responses once detected (Hébert et al., 2019). Diet can influence this behavior:  
140 nutrient-rich diets enhance growth and escape performance (Kloh et al., 2024), whereas  
141 ingestion of toxic cyanobacteria impairs locomotor performance (Moura et al., 2023). Low-  
142 quality diets may therefore compromise escape responses, increasing predation risk.

143 Here, we investigated the interconnected and potentially synergistic effects of diet,  
144 temperature, and the microbiome on the health and behavior of larvae of the European  
145 Common Frog (*Rana temporaria*), an ectothermic model organism. Using a multifactorial  
146 experimental design, we tested whether three diets differing in amounts of protein, fat, and  
147 animal-derived components (low-, intermediate-, and high-quality), two rearing temperatures  
148 (18 °C and 24.5 °C), and exposure to a heat wave (28 °C for 48 h) shaped the gut bacterial  
149 communities of *R. temporaria* larvae. We then linked these experimental conditions - and the  
150 resulting bacterial communities - to food assimilation (isotopic signatures), health biomarkers  
151 (body condition and developmental rate), and behavior, focusing on escape responses to an  
152 aversive stimulus as a proxy for predator avoidance.

153 We tested three hypotheses: (1) diet quality, sustained elevated rearing temperature,  
154 and/or transient heat waves affect gut bacterial diversity and composition, even when  
155 accounting for clutch effects (host genetic background); (2) diet, temperature treatments,  
156 and/or altered gut bacterial communities influence larvae's carbon and nitrogen isotopic  
157 signatures and affect health biomarkers; and (3) diet, temperature treatments, and/or altered  
158 gut bacterial communities lead to differences in behavioral responses to a simulated predator  
159 attack. Finally, we predicted metabolic pathways enriched in bacteria that increased in  
160 abundance under each treatment to identify potential links between microbial activity and  
161 amphibian larval performance.

## 162

### 163 Materials and methods

#### 164

#### 165 *Experimental design*

#### 166

167 Five egg clutches of the European Common Frog (*Rana temporaria*) were collected on  
168 25 March 2023 in the Kleiwiesen (52.328°N, 10.582°E; Braunschweig, Lower Saxony,  
169 Germany) and transported to the Zoological Institute of the Technische Universität  
170 Braunschweig. When hatched larvae reached developmental stage 25 (*sensu* Gosner, 1960)  
171 they were distributed among three food treatments and two controlled-temperature rearing  
172 environments (4 larvae per clutch × 5 clutches × 3 food treatments × 2 rearing temperatures =  
173 120 larvae; Fig. 1).

174 The food treatments were prepared using soluble powdered foods that differed in protein  
175 and fat content, as well as in the diversity of nutrient sources. The diet with the lowest protein  
176 and fat levels and the lowest diversity of components (hereafter "low-quality") consisted of an

177 organic grass powder (NaturaleBio®; *Hordeum vulgare*) containing 3% lipid, 11%  
178 carbohydrate, and 32% protein. The diet with the highest protein and fat content and the  
179 greatest diversity of components (hereafter “high-quality”) was Sera Micron Nature® fish  
180 food, which contains 7.2% lipid, 10.3% carbohydrate, and 56.6% protein. The intermediate  
181 diet (“intermediate-quality”) was a thoroughly blended 1:1 mixture of the powders used for  
182 the low- and high-quality diets.

183 The energy content of each diet was determined by bomb calorimetry (6200 Isoperobol  
184 Calorimeter, Parr Instruments, Moline, Illinois) at the laboratory for chemical analyses at the  
185 University of Hamburg. Mean ( $\pm$  SD) caloric values were  $17.13 \pm 0.04$  kJ/g (n = 3) for the  
186 low-quality diet,  $18.72 \pm 0.03$  kJ/g (n = 3) for the intermediate-quality diet, and  $20.35 \pm 0.06$   
187 kJ/g (n = 4) for the high-quality diet.

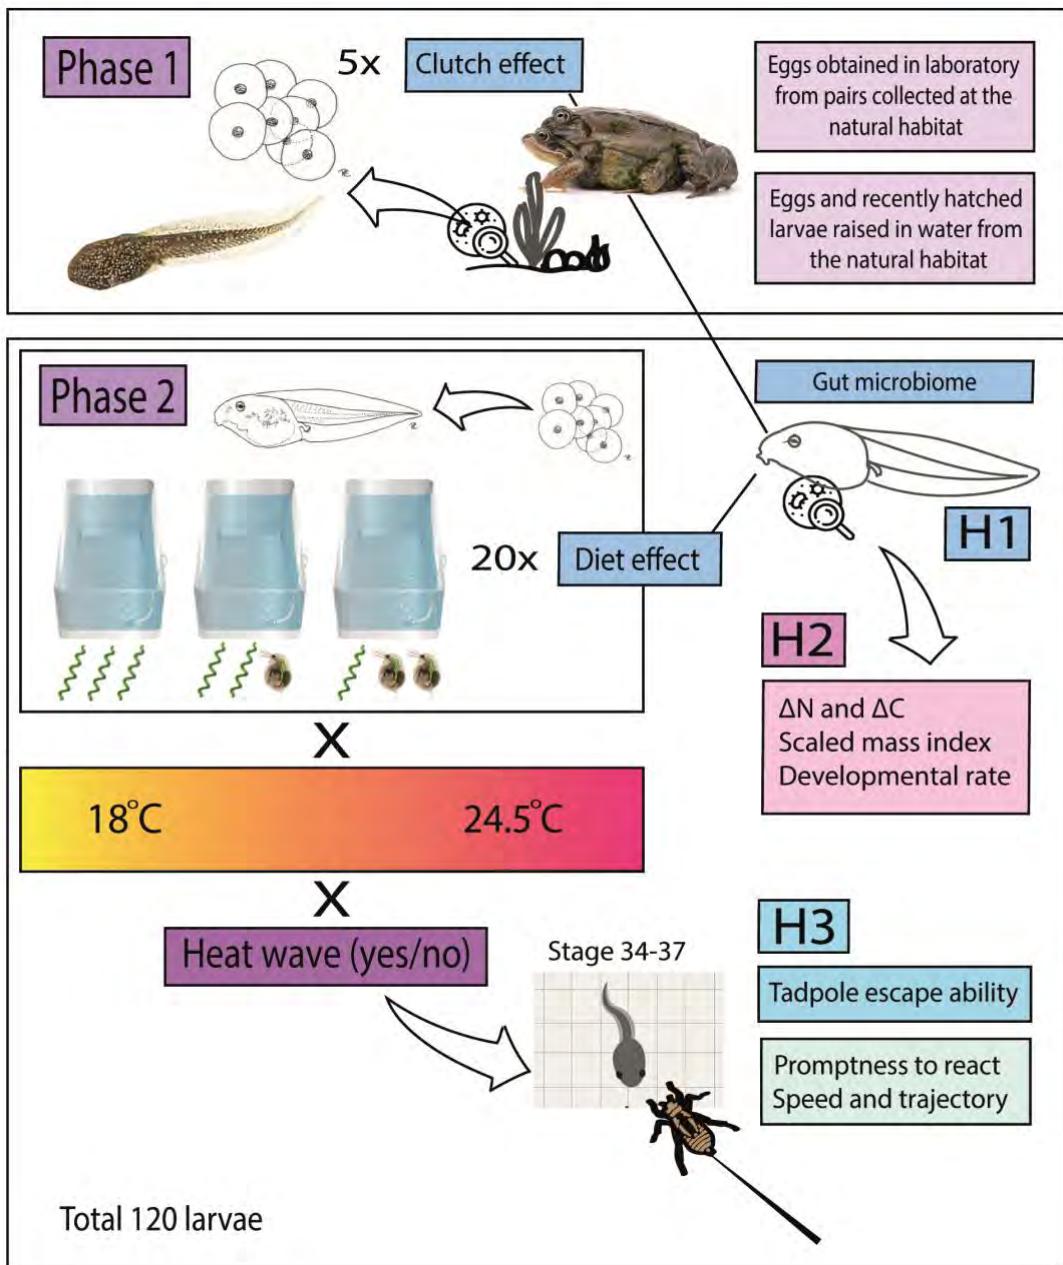

188 The lower temperature (18 °C) represented typical ambient conditions during *R.*  
189 *temporaria* larval development. The higher temperature (24.5 °C) was chosen to fall within  
190 the range of 22-26 °C, in which *R. temporaria* larvae exhibit elevated stress levels but can still  
191 maintain body condition, likely supported by adjustments in their gut bacterial communities  
192 (Eterovick et al., 2024).

193 When larvae reached developmental stages 34–37 (pro-metamorphic stages; digit  
194 development in the hind limbs; *sensu* Gosner 1960), approximately half of the surviving  
195 individuals from each treatment were exposed to a heat-wave protocol to test the effects of  
196 temperature extremes on escape behavior, as well as potential interactions with diet quality  
197 and rearing temperature (Fig. 1). Larvae were kept at 28 °C for 48 h, after which temperature  
198 was decreased at the same rate back to the original rearing temperature. Larvae remained in  
199 their individual buckets throughout the procedure. Additional details on animal husbandry and  
200 experimental setup are available in the supplementary material.

201

202

203

204  
205 Fig. 1. Graphical summary of the experimental design representing acquisition of offspring (larvae)  
206 from five different egg clutches from *Rana temporaria* and the experiment itself. The experiment  
207 structure is shown based on three main hypotheses to be tested: whether diet and temperatures  
208 experienced during development affect assemblage of gut bacteria (H1), nutrient assimilation and  
209 biomarkers (body condition and developmental rate; H2), as well as escape ability of *R. temporaria*  
210 larvae (H3).

211

212

### 213 *Behavioral trials*

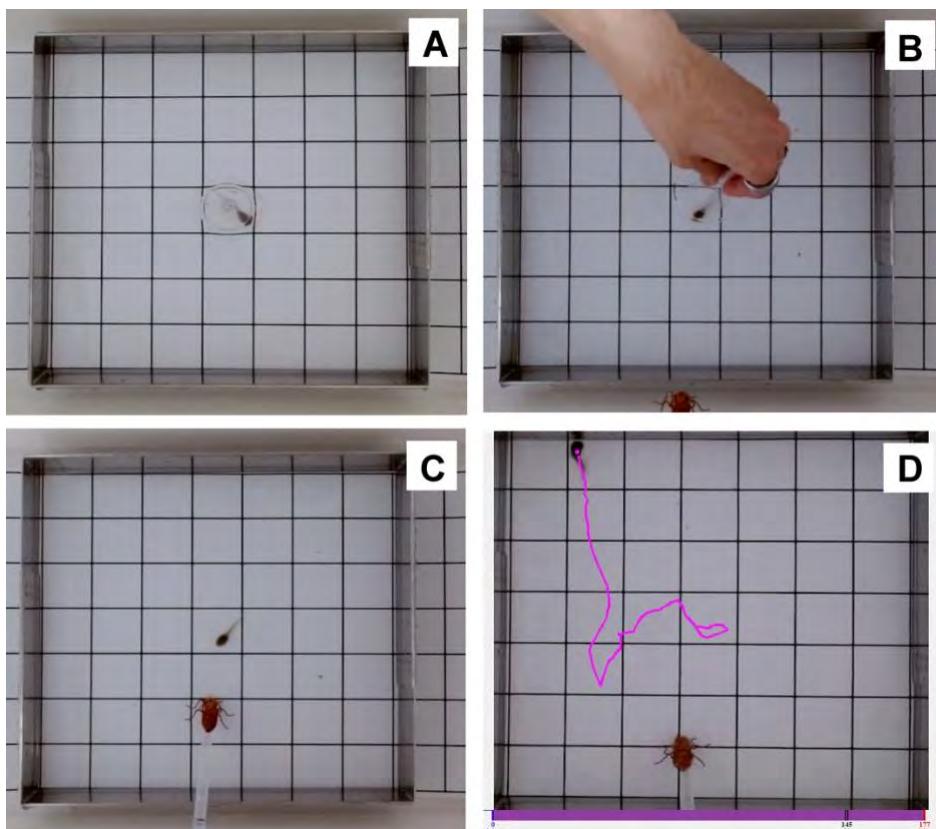

214

215 One day after larvae exposed to the heat wave had returned to their original rearing  
216 temperature, behavioral trials were conducted with both heat-wave and control (non-exposed)  
217 larvae. A white plastic tray (35 × 35 cm) was filled with 1.3 L of rested tap water at the  
218 rearing temperature of the tested larva (18 °C or 24.5 °C), reaching a water depth of 1 cm. A

219 laminated paper marked with  $5 \times 5$  cm squares was placed at the bottom, and an adjustable  
220 metal frame delineated the arena (Fig. 2). The tray was surrounded by white cardboard to  
221 shield larvae from the experimenter, and a high-definition webcam (Logitech C920s HD Pro,  
222 Logitech, Lausanne, Switzerland) was mounted on a tripod directly above the arena.

223 Each larva was gently captured from its bucket using a spoon, placed in the central square  
224 of the arena, and covered with a glass funnel (Fig. 2A). Handling was minimized and  
225 conducted as gently as possible. After a three-minute acclimation period (following Eterovick  
226 et al., 2018), the funnel was removed, and a dragonfly naiad (*Libellula*, Libellulidae,  
227 Anisoptera) model was presented as a potentially aversive stimulus. The stimulus consisted of  
228 a transparent plastic pipette containing 4 mL of water assumed to hold chemical predator  
229 cues. This water was obtained from a 500 mL container where ten dragonfly naiads (*Libellula*  
230 *depressa*; returned to their habitat after use) from the same frog habitat had been held for 4 h.  
231 Each stock of water was used for two hours after removal of the naiads, with water  
232 temperatures matched to the larva's rearing temperature. A life-size predator model, made  
233 from non-toxic modeling clay and ink, was attached to the pipette tip.

234

235  
236

237 Fig. 2. Experimental setup for behavioral tests. Plastic trays filled up to 1 cm with rested tap water at  
238 larvae rearing temperature were lined with a grid of  $5 \times 5$  cm squares. A space of  $35 \times 35$  cm was  
239 delimited with a metal frame and the larva to be tested was placed at the central square, where it was  
240 retained for 3 minutes under a glass funnel (A). After careful removal of the funnel without disturbing  
241 the larva (B), a predator model was approached (C) and the reaction of the larva was filmed to  
242 evaluate the escape response (see text for details). Fleeing trajectories of the larva were tracked with  
243 the software AnimalTA (Chiara and Kim, 2023; D).

244

245        Immediately after funnel removal, the pipette was inserted at ~45° relative to the larva's  
246        frontal direction, touching the water two grid squares (10 cm) away. Water containing  
247        predator cues was slowly released, and the predator model was gradually moved toward the  
248        larva until it elicited an escape response or gently touched it. Because amphibian larvae  
249        perceive varied cues from predators (Melo et al., 2021), this combined stimulus was designed  
250        to engage visual (model), mechanical (approach and water flow), and chemical (predator  
251        exposed water) cues, as the most relevant cue for *R. temporaria* larvae is unknown. Trials  
252        ended once the larva attempted to flee or if the model touched the larva without eliciting any  
253        escape movement. Video recordings were captured using OBS Studio (Open Broadcaster  
254        Software, Version 29.1; <https://obsproject.com/>). Larvae were tested in random order, blind to  
255        their heat-wave exposure and rearing conditions.

256        Videos were analyzed in random order and without treatment information using  
257        AnimalTA software (Chiara and Kim, 2023). Occasionally, larvae moved during funnel  
258        removal and had to be repositioned in the arena's center. We recorded the "number of  
259        attempts" (times a larva was repositioned) as an additional variable, reflecting early  
260        movements that could contribute to energy expenditure and stress. To ensure uniformity, we  
261        quantified the elapsed time between funnel removal and the trial start (when the predator  
262        model contacted the water) and found it to be strongly correlated with the number of  
263        repositioning attempts (Spearman's  $Rs = 0.9$ ,  $p < 0.001$ ; Fig. S1), indicating no significant  
264        variation in attempt durations.

265        Escape behavior was quantified using the following variables: (1) whether the larva  
266        reacted (fleeing) or not, with no reaction defined as remaining stationary even when touched  
267        by the model; (2) reaction time, measured from the moment the predator model touched the  
268        water until the larva's flee response; (3) whether the larva reacted before or after contact with  
269        the predator model; (4) average speed; and (5) trajectory linearity ("meander" function,  
270        Chiara and Kim, 2023) during fleeing. Variables 2–5 were analyzed only for larvae exhibiting  
271        escape responses. Speed and trajectory linearity were measured until the larva stopped or  
272        touched a wall, as such a barrier would otherwise bias the metrics.

273        This behavioral test protocol was used to examine the effects of diet, rearing temperature,  
274        and heat-wave exposure on larval kinematics. We expected larvae fed higher-quality diets,  
275        reared at 18 °C, and not exposed to the heat wave to be more alert and reactive, fleeing earlier  
276        and at higher speed. Escape trajectories were expected to be more curved, reflecting the  
277        typical anti-predator strategy of anuran larvae, which rely on rapid turns with small radii  
278        rather than straight-line swimming (Wassersug, 1989). Simply stated, tadpoles typically  
279        escape from predatory attacks by turning away from the approaching predator rather than  
280        trying to outrun it (Wassersug, 1989).

281  
282        *Sample collection*  
283

284        Within 12 hours after the behavioral trials, each tadpole was euthanized using 2 g × L<sup>-1</sup>  
285        tricaine methanesulfonate (MS-222; Ethyl 3-aminobenzoate methanesulfonate; Sigma-  
286        Aldrich). The developmental stage of each larva was confirmed under a stereomicroscope  
287        according to Gosner (1960). Snout-vent length (SVL) was measured to the nearest 0.5 mm

288 using a digital caliper. Larvae were then gently dry-blotted and weighed to the nearest 0.001 g  
289 using an electronic balance (Sartorius A200 S, Germany).

290 A sterile scalpel was used to excise the tail for subsequent isotopic analysis. Using a  
291 sterile scalpel and tweezers, the ventral skin was cut to remove the entire gut for bacterial  
292 DNA extraction. The tail, gut, and remaining body were placed in three separate tubes, all  
293 stored at -80 °C until further analysis.

294

295 *Isotope analyses*

296

297 Stable isotope analyses were conducted to assess differences in absorption and  
298 incorporation of food components by larvae subjected to different diets, based on isotopic  
299 signatures. Analyses were performed at the Biozentrum Klein Flottbek, University of  
300 Hamburg, Germany, following the methods of Glos et al. (2020), as detailed in the  
301 supplementary material.

302

303 *Body condition and developmental rate assessment*

304

305 Body condition was estimated using the scaled mass index (SMI), calculated from the  
306 slope of the regression of log-transformed snout-vent length (SVL) and log-transformed body  
307 mass (standardized major axis, SMA) as:  $SMI = [individual\ Mass \times (mean\ SVL\ of\ population/individual\ SVL)^{SMA}]$  (Peig and Green, 2009; 2010).

309 This index has been previously applied to *R. temporaria* larvae (Dittrich et al., 2018;  
310 Ruthsatz et al., 2020; Eterovick et al., 2024). In the present study, SMA was 2.742.

311 Developmental rate was calculated as the number of Gosner (1960) stages advanced by  
312 each larva divided by the number of days from hatching to the end of the experiment.

313

314 *Bacterial 16S rRNA gene library preparation*

315

316 DNA was extracted using the QIAamp Fast DNA Stool Mini Kit (QIAGEN) following  
317 the manufacturer's instructions. Extractions were performed over five days, with one negative  
318 control included per day to monitor for contamination. A ZymoBIOMICS™ microbial  
319 community standard (Zymo Research Europe GmbH) was used as a positive extraction  
320 control on the first and last days of the extraction process.

321 The V4 region of the 16S rRNA gene was amplified using the forward primer 515F (5'-  
322 GTGCCAGCMGCCGCGGTAA-3') and reverse primer 806R (5'-  
323 GGACTACHVGGGTWTCTAAT-3'; Caporaso et al., 2011). Each sample was tagged with a  
324 unique combination of forward and reverse primers from a stock of 24 forward and 24 reverse  
325 primer tags. Two PCR plates were prepared, each including one negative control. A positive  
326 control consisting of ZymoBIOMICS™ microbial community DNA standard was also  
327 included. The Zymo microbial community and DNA standards, which contain known species

328 compositions and abundances, were used to verify the precision of extraction and PCR  
329 protocols, respectively.

330 PCR products were pooled and purified. Aliquots were electrophoresed on a 2% agarose  
331 gel, and the desired 251 bp fragment was extracted using the Monarch DNA Gel Extraction  
332 Kit (New England BioLabs, GmbH, Germany) following the manufacturer's protocol.  
333 Purified DNA was quantified with a Qubit™ fluorometer (Invitrogen) and sequenced using  
334 the MiSeq500 Illumina platform (paired-end 2 × 250 bp, v2 chemistry) at the Leibniz-Institut  
335 DSMZ - German Collection of Microorganisms and Cell Cultures GmbH.

336  
337 *Bioinformatic analyses*  
338

339 Sequence denoising, filtering, and alpha and beta diversity analyses were performed in  
340 QIIME2 (Bolyen et al., 2019). Details on sequence quality filtering, sample depth and  
341 taxonomic assignment are provided as supplementary material.

342 Beta diversity was assessed using unweighted UniFrac distances and compared among  
343 treatments using PERMANOVA with pairwise post hoc tests. Metagenomic functional  
344 predictions of the gut microbiota were generated using PICRUSt2 (Douglas et al., 2020).

345  
346 *Statistical analyses*  
347

348 Isotopic signatures were compared among diet treatments and between rearing  
349 temperatures using the R package nicheROVER (Swanson et al., 2015; R Core Team, 2024).  
350 This approach estimates the probability that the isotopic niches of individuals from one group  
351 overlap with those of another, based on quantitative variables such as  $\delta^{15}\text{N}$  and  $\delta^{13}\text{C}$ . We ran  
352 1,000 simulations to calculate niche breadth and overlap. Isotopic signatures of the three diets  
353 were based on six replicate samples per food type.

354 The effects of food treatment, rearing temperature, and heat-wave exposure - including  
355 all two- and three-way interactions - on larval body condition and developmental rate were  
356 analyzed with GLMMs in the afex package (Singmann et al., 2024), with clutch identity  
357 included as a random factor.

358 Before analyzing behavioral traits, we screened for outliers in the time elapsed between  
359 the moment the predator model touched the water and when it touched the larva (where  
360 applicable). Two outliers with unusually long times (Fig. S2) were removed. For the  
361 remaining data, this interval averaged  $7.44 \pm 1.78$  s. Mixed models were then built to test the  
362 influence of food treatment, rearing temperature, and heat-wave exposure (fixed variables),  
363 including their interactions, on: (1) whether the larva reacted (binary), (2) reaction time, (3)  
364 whether the reaction occurred before or after being touched (binary), (4) average speed, and  
365 (5) trajectory linearity (see "Behavioral trials"). Trial day and clutch identity were included as  
366 random effects nested within food treatment. When full models failed to converge due to  
367 model complexity, we simplified random-effect structures or analyzed likely interactions  
368 separately (Singmann et al., 2024). For binary outcomes, singular-fit warnings were expected,  
369 but results were considered robust when outcomes were consistent across full and simplified

370 models (Singmann & Kellen, 2019; Singmann et al., 2024). Post hoc tests were performed  
371 with emmeans (Lenth, 2017).

372 For each behavioral variable, we first tested whether larval mass, body condition, or  
373 number of positioning attempts influenced results (Pearson or Spearman correlations for  
374 quantitative variables; Wilcoxon tests for binary outcomes). When relevant, these variables  
375 were incorporated into the models (e.g., number of attempts as a random factor). We expected  
376 larvae in better condition to respond more rapidly and before being touched, and to escape  
377 with higher speed and less linear trajectories. Positioning attempts were considered  
378 problematic if they were associated with reduced responsiveness, delayed reactions, increased  
379 likelihood of being touched, slower speeds, or more linear escapes.

380 Microbiome  $\alpha$ -diversity (Shannon entropy) was analyzed with GLMMs in afex, using  
381 food treatment, rearing temperature, and heat-wave exposure (and all interactions) as fixed  
382 effects and clutch identity as a random effect.

383 To assess microbiome composition, we constructed a phyloseq object (McMurdie &  
384 Holmes, 2013) normalized via Total Sum Scaling (TSS) and tested for differential microbial  
385 markers across the 12 treatment combinations (3 diets  $\times$  2 rearing temperatures  $\times$  heat-wave  
386 vs. no heat-wave). Variance homogeneity among groups was evaluated with betadisper  
387 (vegan; Oksanen et al., 2013), and ASV abundances were ordinated using PCoA. Microbiome  
388 biomarkers were identified through LEfSe (Segata et al., 2011) using the R package  
389 microbiomeMarker (Cao et al., 2022), with an LDA score threshold of 4. LEfSe identifies  
390 taxa most likely to explain group-level differences while accounting for statistical  
391 significance.

392 Predicted microbial metabolic pathways were compared among all 12 treatment  
393 combinations using ggpicrust2 (Yang et al., 2023), applying the ALDEx2 method for multi-  
394 group comparisons.

395

## 396 **Results**

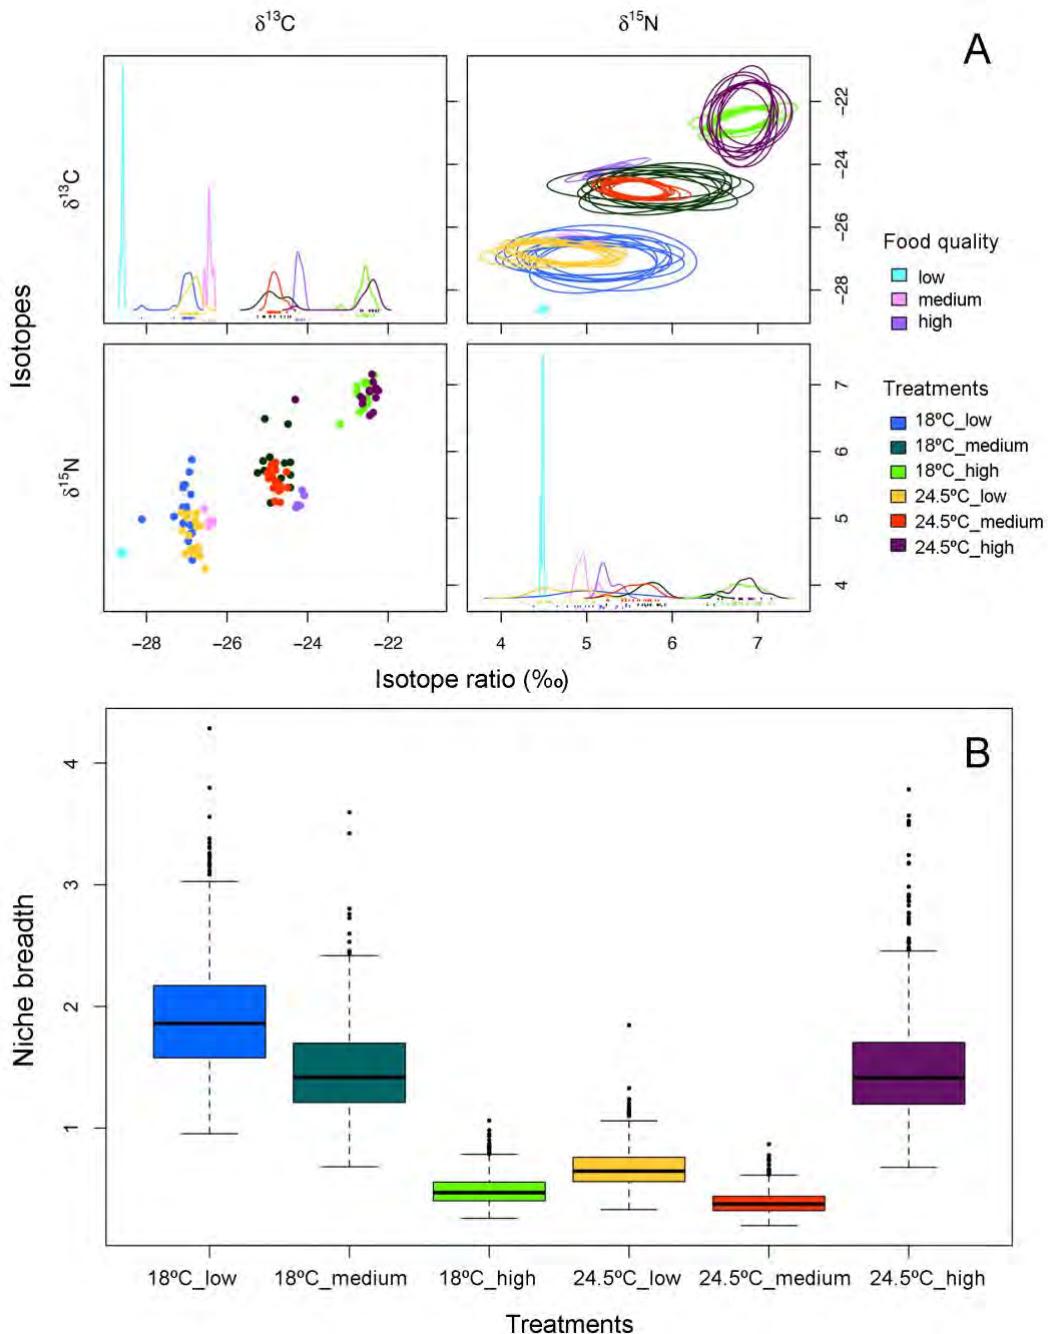

397

### 398 *Isotope analyses*

399

400 The three diets produced markedly different isotopic signatures in *Rana temporaria*  
401 larvae, whereas isotopic niches of the two temperature treatments largely overlapped within  
402 each diet (Figs. 3, S3). For the low- and intermediate-quality diets, higher temperature  
403 reduced isotopic niche breadth. In contrast, for the high-quality diet, niche breadth was  
404 narrower at 18 °C and increased at 24.5 °C (Fig. 3).

405

406  
 407 Fig. 3. Isotopic signatures (A) and niche breadth (B) of *Rana temporaria* larvae reared with three food  
 408 treatments and two temperatures in a crossed experimental design. Food treatments correspond to diets  
 409 with increasing levels of protein, fat, and components of animal origin (their isotopic signatures are  
 410 also included in A). Rearing temperatures were  $18^\circ\text{C}$  and  $24.5^\circ\text{C}$ . The isotopic signatures are  
 411 represented as lines in one-dimensional density plots (top left and bottom right graphs, A), two-  
 412 dimensional scatterplots (bottom left graph; A) and ten random elliptical simulated projections of  
 413 trophic niches corresponding to each diet and each treatment (top right graph; A).

414  
 415 *Survivorship, development, and body condition*

416  
 417 Of the 120 larvae used in the experiment, 12 died: six in the  $18^\circ\text{C}$  treatment (five with  
 418 intermediate- and one with high-quality food) and six in the  $24.5^\circ\text{C}$  treatment (five with high-  
 419 and one with intermediate-quality food). Five of these deaths occurred during or after the

420 heat-wave phase (three heat-wave larvae and two controls). One larva developed hydrops and  
421 was excluded.

422 Larval body condition (SMI) did not differ among food treatments, rearing  
423 temperatures, or heat-wave exposure; the same was true for body mass alone (Table 1, Figs.  
424 S4, S5). In contrast, developmental rate was higher at 24.5 °C than at 18 °C (Table 1). At 24.5  
425 °C, developmental rate also increased with intermediate-quality food (Kenward–Roger post-  
426 hoc: estimate = -0.029, SE = 0.010, df = 91.5, t = -2.874, p = 0.025) and with high-quality  
427 food (estimate = -0.054, SE = 0.011, df = 92.0, t = -4.804, p < 0.001) compared with low-  
428 quality food. These effects were absent at 18 °C (Table 1; Figs. 4A, S6).

429  
430 *Behavioral trials*  
431

432 Escape-behavior trials were conducted with 102 *R. temporaria* larvae. Of the 108  
433 surviving larvae, one showed hydrops and four displayed abnormal behavior (lethargy or  
434 irregular swimming) and were therefore excluded. In addition, one video file was accidentally  
435 lost. Of the 102 larvae tested, 81 responded to the aversive stimulus (61 before being touched  
436 by the predator model and 20 upon contact), whereas 21 did not react even when gently  
437 touched.

438  
439 *Larvae likeliness to react*  
440

441 Larval response (reacted vs. did not react) was unrelated to mass (W = 711.5, p = 0.252;  
442 Fig. S7) or body condition (W = 936, p = 0.482; Fig. S8). The number of attempts needed to  
443 position a larva before the trial differed between responders and non-responders (W = 601, p  
444 = 0.022; Fig. S9); however, larvae requiring more positioning attempts were also more likely  
445 to react, indicating that repositioning did not impair their ability to respond (Fig. S9). For this  
446 reason, number of attempts was included as an additional random effect in the models  
447 assessing reaction likelihood.

448 Reaction likelihood was not explained by any fixed factor alone but by interactions  
449 among them (Table 2). The full mixed-effects model with random structure did not converge,  
450 so we ran a model without random effect structure using the *lmer* function (Table 2). Simpler  
451 models including only individual predictors and single interactions yielded consistent results  
452 using the mixed function.

453 Larvae reared on high-quality food were more likely to react than those fed  
454 intermediate-quality food at 24.5 °C (free-method post-hoc: estimate = -0.379, SE = 0.124, df  
455 = 86.8, t = -3.059, p = 0.013) and not exposed to the heat wave (estimate = -0.379, SE =  
456 0.126, df = 80.9, t = -3.011, p = 0.015; Fig. 4B). Heat-wave exposure increased reaction  
457 likelihood only at 24.5 °C, whereas at 18 °C it reduced the likelihood of reacting (Fig. 4B,  
458 Table 2; see Fig. S10 for residual diagnostics).

459

460 Table 1. Models built to explain variability in body condition (SMI), mass, developmental rate (dev\_rate) and gut bacteria diversity of *Rana*  
 461 *temporaria* larvae reared at two temperatures (either 18 °C or 24.5 °C) and receiving one of three food treatments considered as of low-, medium-,  
 462 and high-quality (based on increasing content of protein, fat, and animal components) in a crossed experimental design. Developmental rate was  
 463 calculated as the number of Gosner's (1960) developmental stages advanced during the experiment divided by the number of days from hatching to  
 464 the end of the experiment. Significant effects are boldfaced and marked with an \*. *mixed* refer to function employed to run the models.

476 Table 2. Models built to explain variability in five dependent variables describing *Rana temporaria* larvae escaping behavior when exposed to an  
 477 aversive stimulus consisting of an approaching transparent plastic pipette with a predator model glued to the top releasing 4 ml of water previously  
 478 exposed to predators. Analyzed escape responses were: (1) whether the larva reacted or not (no reaction meant not moving even when touched by  
 479 the model), (2) larvae reaction time (time elapsed from the moment the predator model touched the water to the fleeing response of the larva), (3)  
 480 whether the larva reacted before or after being touched by the predator model, (4) average speed and (5) trajectory linearity while fleeing. *Rana*  
 481 larvae were reared at two temperatures (either 18 °C or 24.5 °C) and received one of three food treatments considered as of low,  
 482 medium, and high quality (based on increasing levels of protein, fat, and components of animal origin) in a crossed experimental design. Significant  
 483 effects are boldfaced and marked with an \*. *mixed* and *lmer* refer to functions employed to run the models.

Fig. 4. Interactive effects among food quality, rearing temperature, and exposure to a heat wave in *Rana temporaria* larvae developmental rate (A), variables describing behavior (B, D) and gut bacteria diversity (C). Food quality refers to increasing levels of protein, fat, and components of animal origin. Rearing temperatures were 18 °C and 24.5 °C. The heat wave corresponded to increasing temperature at a ramping rate of 0.5 °C per hour until 28 °C, maintenance at 28 °C for 48 h and subsequent temperature decrease of 0.5 °C per hour until original rearing temperature. Variables describing behavior are larvae likeliness to react (fleeing) to an aversive stimulus (B) and to be touched by an approaching predator model before reacting (D). Graphs correspond to violin plots of estimated marginal means from the corresponding model (see Table 1).

496

#### 497      *Larvae reaction time*

498      Reaction time, measured for the 81 larvae that responded to the stimulus, was not  
499 influenced by mass (Adjusted  $R^2 = 0.030$ ,  $F_{79} = 3.487$ ,  $p = 0.066$ ; Fig. S11), body condition  
500 (Adjusted  $R^2 = -0.013$ ,  $F_{79} = 0.005$ ,  $p = 0.946$ ; Fig. S12), or the number of positioning  
501 attempts before the trial ( $p = -0.125$ ,  $p = 0.263$ ; Fig. S13). Reaction time was also unaffected  
502 by any experimental factor - food treatment, rearing temperature, heat-wave exposure - or by  
503 their interactions (Table 2).

504

#### 505      *Larvae likeliness of being touched*

506      Whether larvae reacted before or after being touched by the predator model was  
507 unrelated to mass ( $W = 577$ ,  $p = 0.722$ ; Fig. S14), SMI ( $W = 697$ ,  $p = 0.343$ ; Fig. S15), or the  
508 number of attempts needed to position them ( $W = 533$ ,  $p = 0.366$ ; Fig. S16). In contrast,

509 reaction depended on food treatment, its interaction with heat-wave exposure, and the three-  
510 way interaction among food treatment, rearing temperature, and heat-wave exposure (Table 1;  
511 Fig. S17). At 24.5 °C, larvae fed intermediate-quality food were more likely to be touched  
512 before fleeing than those fed high-quality food (free method post-hoc: estimate = 1.021, SE =  
513 0.334,  $z = 3.059$ ,  $p = 0.025$ ; Fig. 4D), although this pattern did not occur in larvae exposed to  
514 the heat wave.

515

#### 516 *Larvae escape speed and trajectory*

517 Escape speed and movement non-linearity (“meander”; Chiara & Kim, 2023) were  
518 quantified for the 81 larvae that fled, with both variables log-transformed to meet normality  
519 assumptions. Neither metric was affected by mass, body condition, or the number of  
520 positioning attempts (speed: Adjusted  $R^2 = -0.013$ ,  $F_{79} = 0.004$ ,  $p = 0.949$ ; Fig. S18; Adjusted  
521  $R^2 = -0.013$ ,  $F_{79} = 0.009$ ,  $p = 0.923$ ; Fig. S19;  $\rho = -0.104$ ,  $p = 0.354$ ; Fig. S20; meander:  
522 Adjusted  $R^2 = 0.003$ ,  $F_{79} = 1.271$ ,  $p = 0.263$ ; Fig. S21; Adjusted  $R^2 = -0.009$ ,  $F_{79} = 0.247$ ,  $p =$   
523 0.620; Fig. S22;  $\rho = 0.050$ ,  $p = 0.657$ ; Fig. S23). Food treatment, rearing temperature, heat-  
524 wave exposure, and their interactions likewise had no effect on larval escape speed or  
525 trajectory (Table 2).

526

#### 527 *Gut bacteria diversity and composition*

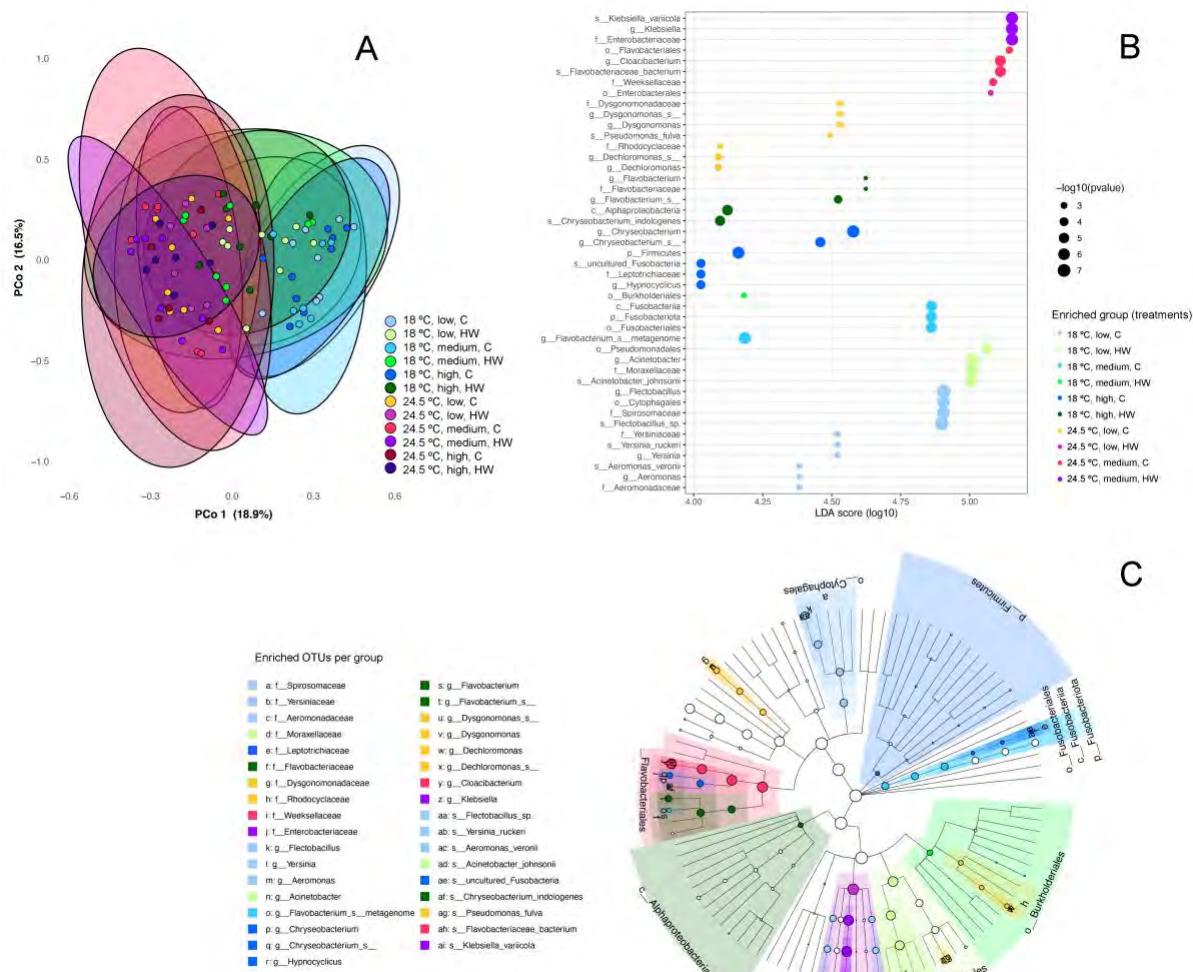

528

529 Gut bacterial diversity was influenced by food treatment, rearing temperature, their  
530 interaction, and the three-way interaction with heat-wave exposure (Table 1). Larvae fed  
531 medium-quality food exhibited reduced gut bacterial diversity compared to larvae fed low-  
532 quality food, but only when reared at 24.5 °C and exposed to a heat wave (Fig. 4C).

533 The two positive extraction controls (ZymoBIOMICSTM microbial community standard)  
534 and the positive PCR control (ZymoBIOMICSTM microbial community DNA standard)  
535 displayed identical species compositions but differed in the relative abundances of taxa  
536 compared with the manufacturer’s expected profile (Fig. S24). The two extraction controls  
537 yielded consistent results (Fig. S24), indicating that any deviations in relative abundances  
538 were systematic rather than random.

539 In total, 207 Operational Taxonomic Units (OTUs) were recovered from the gut  
540 microbiomes of 92 *R. temporaria* larvae. The dominant phyla across treatments were  
541 *Pseudomonadota* and *Bacteroidota* (Fig. S25). Most treatment pairs differed significantly in  
542 gut bacterial community composition, with a few exceptions. No differences were detected  
543 between medium-quality food with heat-wave exposure and high-quality food without  
544 exposure at 18 °C. At 24.5 °C, larvae fed low-quality food with heat-wave exposure did not  
545 differ from those fed medium-quality food (with or without heat-wave exposure) or high-  
546 quality food (with or without heat-wave exposure) (Fig. 5A; Table S1).

547

548

549 Fig. 5. Gut bacteria community composition (A) and enriched Operational Taxonomic Units (OTUs; 550 B) according to treatments imposed to larvae of *Rana temporaria*, corresponding to three diets with 551 increasing levels of protein, fat, and components of animal origin (low-, medium-, and high-quality), 552 two rearing temperatures (18 °C and 24.5 °C) and exposure or not to a heat wave (HW vs. C = 553 control). Clustering of taxa with differences in abundance among treatments is also shown (C). Colors 554 of OTUs correspond to colors of treatments in which they were the most abundant, cold colors (blue- 555 green) correspond to 18 °C and warm colors (yellow-purple) to 24.5 °C rearing temperatures. Color 556 intensity increases with food quality.

557

558

559 All treatment combinations except those involving high-quality food at 24.5 °C 560 (regardless of heat-wave exposure) had OTUs identified as biomarkers, totaling 45 OTUs 561 (Fig. 5). At low food quality, the main biomarkers at 18 °C without heat-wave exposure were 562 *Flectobacillus* (*Spirosomaceae*, *Cytophagales*), *Yersinia ruckeri* (*Yersinaceae*), and 563 *Aeromonas veronii* (*Aeromonadaceae*). When exposed to a heat wave, *Acinetobacter* 564 *johsonii* (*Moraxellaceae*) was predominant. At 24.5 °C, *Dysgonomonas* 565 (*Dysgonomonadaceae*), *Pseudomonas fulva*, and *Dechloromonas* (*Rhodocyclaceae*) 566 dominated without heat-wave exposure, whereas *Enterobacteriales* predominated under heat- 567 wave exposure.

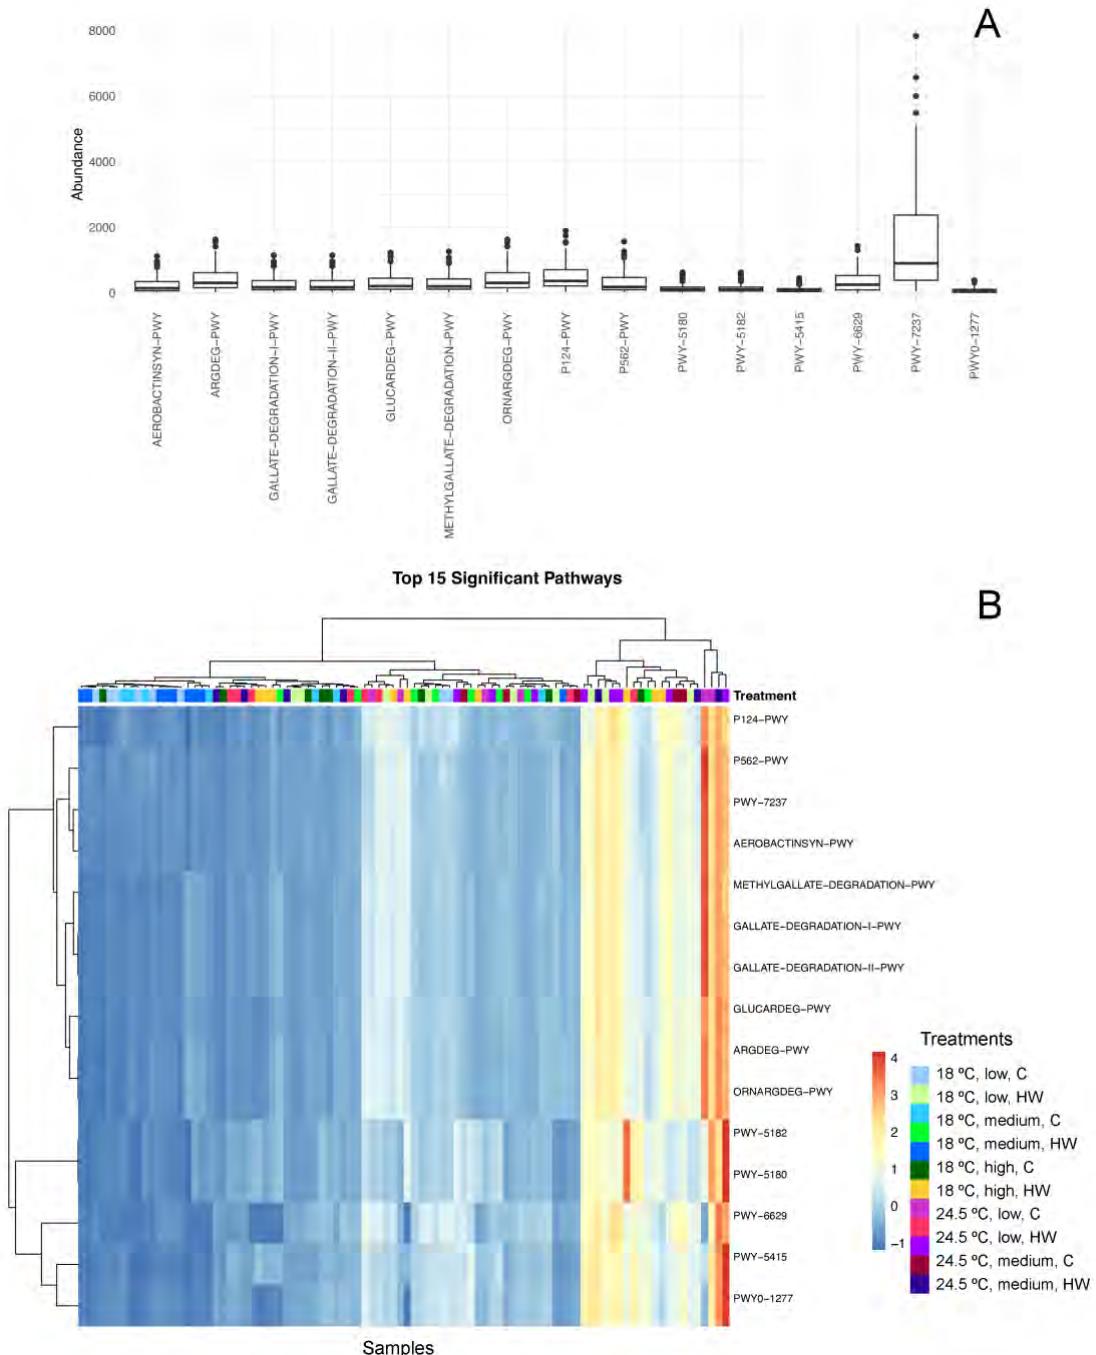

568 At intermediate food quality, *Fusobacteriales* (*Fusobacteriia*, *Fusobacteriota*) and  
569 *Flavobacterium* were characteristic at 18 °C without heat-wave exposure, while  
570 *Burkholderiales* dominated with heat-wave exposure. At 24.5 °C, *Cloacibacterium*  
571 (*Weeksellaceae*, *Flavobacteriales*) predominated without heat-wave exposure, whereas  
572 *Klebsiella variicola* (*Enterobacteriaceae*) was selected as a biomarker under heat-wave  
573 exposure.

574 At high food quality and 18 °C, *Chryseobacterium*, *Bacillota*, and *Hypnocyclus*  
575 (*Leptotrichiaceae*) were biomarkers without heat-wave exposure, and *Cryseobacterium*  
576 *indologenes*, *Flavobacterium* (*Flavobacteriaceae*), and *Alphaproteobacteria* predominated  
577 under heat-wave exposure (Fig. 5).

578 In total, 357 unique metabolic pathways were predicted, of which 289 differed  
579 significantly among experimental treatments. The most significantly affected pathways  
580 included degradation of myo-inositol, D-glucarate, fructose, and various aromatic compounds  
581 (catechol, gallate, toluene, 3-phenylpropanoate, and 3-(3-hydroxyphenyl)propanoate), as well  
582 as synthesis of L-tryptophan and aerobactin, and conversion of amino acids into putrescine  
583 (Fig. 6A).

584 Larvae clustered into four major groups based on the top 15 significantly differing  
585 pathways (Fig. 6B). One group showed under-expression across all pathways and consisted  
586 mostly of larvae reared at 18 °C without heat-wave exposure, although individuals from other  
587 treatment categories were also included. A second group showed intermediate expression and  
588 was highly heterogeneous across food treatments, temperatures, and heat-wave exposure. The  
589 two groups with the highest predicted pathway expression were composed predominantly of  
590 larvae reared at 24.5 °C, exposed to a heat wave, or both (Fig. 6B).

## Discussion

601  
602  
603  
604  
605

The gut microbiome plays key roles in many aspects of animal biology, from nutrient assimilation to immune defense and ultimately behavior (McFall-Ngai et al., 2013; Tuddenham and Sears, 2015). Animals respond to environmental conditions and their gut microorganisms are also expected to respond, potentially in ways that are adaptive and

606 enhance the animals' ability to cope with both natural environmental fluctuations (Park and  
607 Do, 2024) and human-driven environmental challenges (Lynch and Hsiao, 2019; Fontaine and  
608 Kohl, 2023). Under changing conditions, microbial taxa favored by the new environment may  
609 increase in abundance and help maintain host metabolic functions, provided that the microbial  
610 community has sufficient functional redundancy (Louca et al., 2018).

611 In our study, larvae of *R. temporaria* exposed to different temperatures and diets  
612 exhibited shifts in gut bacterial diversity and composition, likely enabling them to maintain  
613 body condition and still develop faster under higher temperatures. At elevated temperatures,  
614 diet quality became a decisive factor for larval development and escape performance.  
615 Moreover, both long-term warming and short heat waves appeared to induce changes in the  
616 microbiome that, in turn, influenced the larvae's ability to react.

617

#### 618 *Larvae nutrient assimilation, growth, and development*

619 Larvae of *Rana temporaria* exhibited clearly distinguishable stable isotope signatures  
620 depending on food treatment, reflecting expected differences in nutrient acquisition from the  
621 diets provided. However, body condition did not differ among food treatments, regardless of  
622 rearing temperature. Development, on the other hand, was faster at 24.5 °C, and at this  
623 temperature, higher food quality further increased developmental rate. Because temperature  
624 determines the metabolic rate of ectotherms (Álvarez and Nicieza, 2002) and higher  
625 metabolism requires more energy (Arendt, 1997), the improved food quality likely enabled *R.*  
626 *temporaria* larvae to grow faster while maintaining good body condition.

627 The “macronutrient ratio hypothesis” predicts that ectotherms prefer increased  
628 carbohydrate/protein ratios at higher temperatures to meet the energetic demands of elevated  
629 metabolism, because excreting nitrogen from protein catabolism incurs a cost (Hardison and  
630 Eliason, 2024). Similarly, the “temperature metabolic stoichiometry hypothesis” proposes that  
631 ectotherms prefer diets with a higher carbon-to-nitrogen ratio under elevated temperatures  
632 (Hardison and Eliason, 2024). Nitrogen excretion rates, however, usually increase with  
633 temperature, reducing the cost of protein-rich diets (Hardison and Eliason, 2024). This  
634 increase in nitrogen excretion may have allowed *R. temporaria* larvae to maintain body  
635 condition and develop faster at higher temperatures when fed high-protein diets with  
636 relatively constant carbohydrate content. A proportional increase in protein consumption at  
637 higher temperatures has been observed in arthropods (Devries and Appel, 2014; Schmitz et  
638 al., 2016), and invertebrates can maintain stable carbon-to-nitrogen ratios if food intake  
639 increases with temperature (Anderson et al., 2017). In our study, this was likely the case  
640 because larvae were fed *ad libitum*.

641 Niche breadth, based on stable isotope analyses, was higher at 18 °C with low to  
642 intermediate food quality and at 24.5 °C with high food quality. Because food within  
643 treatments was uniform, niche breadth reflects individual variability in the assimilation of  
644 food components, which may indicate microbiome-mediated modulation (discussed below).  
645 Niche breadth was markedly lower at 18 °C with high food quality and at 24.5 °C with  
646 intermediate food quality. Low-quality food resulted in intermediate niche breadths at 24.5 °C.  
647 The microbiome is modulated by diet and host genetics and, in turn, can influence nutrient

648 absorption and host metabolism (Huda et al., 2022; Corbin et al., 2023). Thus, broader niches  
649 within treatments may reflect greater plasticity of the holobiont (i.e., microbiome–host  
650 association) in adjusting nutrient absorption at the individual level.

651 More diverse microbial communities are likely to possess higher functional redundancy,  
652 allowing metabolic functions to be maintained despite changes in the abundance of specific  
653 taxa (Louca et al., 2018). In humans, distinct well-balanced host–microbial symbiotic states  
654 have been identified, and these states respond differently to diet (Arumugam et al., 2011).  
655 Such plasticity may allow the holobiont to meet the nutritional demands of the host,  
656 depending on the interaction between the microbiome and host genetic background. In our  
657 study, host genetic variability was unlikely to differ among treatments, which contained equal  
658 numbers of larvae from five clutches. Therefore, the larger niche breadths observed in some  
659 treatments may indicate a higher adaptive capacity of the microbiome to interact with host  
660 genetics and enhance host performance, which could be beneficial.

661 If this hypothesis holds, higher efficiency in individual food assimilation could be  
662 achieved at 24.5 °C when larvae consume high-quality food, as suggested by the observed  
663 faster development without detriment to body condition or escape performance (discussed  
664 below). However, in natural habitats, *ad libitum* access to the highest-quality food at elevated  
665 temperatures may not be realistic. In such circumstances, herbivorous diets - which resulted in  
666 broader niches than diets with intermediate animal components in our experiment - may  
667 represent the best available solution. Therefore, dietary preferences toward herbivory under  
668 heat stress could be subject to selection. In the wild, plant material has been associated with  
669 higher nutritional value for fish at warmer temperatures and is thought to influence latitudinal  
670 diversity gradients in herbivorous versus carnivorous fishes, with consumption of plant-based  
671 food increasing with temperature (Behrens and Lafferty, 2007; González-Bergonzoni et al.,  
672 2012). Choice experiments with ectotherms have similarly shown selection for more  
673 herbivorous diets at higher temperatures (Vejříková et al., 2016; Zhang et al., 2020). Yet, in  
674 some cases, herbivorous fish abundance did not increase with temperature in the southern  
675 hemisphere (Trip et al., 2014), and grasshoppers increased preference for protein under higher  
676 temperatures (Schmitz et al., 2016), indicating that increased plant consumption is not the  
677 only strategy for coping with heat. The availability of suitable microorganisms to aid  
678 digestion and assimilation of different nutrients, along with their own response to  
679 temperature, is therefore critical for host success at varying temperatures and food qualities  
680 (Vejříková et al., 2016).

681 Increasing temperatures can alter the diets of ectothermic animals by affecting both food  
682 availability and quality or by triggering dietary shifts (Hardison and Eliason, 2024). For  
683 instance, lipid content of algae decreases at higher temperatures (20–28 °C vs. 12 °C), which  
684 also reduces the growth of *Daphnia* fed on them (Tseng et al., 2021). Altered temperatures  
685 impose different nutrient demands, and species may adjust foraging behavior accordingly.  
686 Thus, understanding the nutrients ectotherms can actually access in natural habitats is crucial  
687 for interpreting laboratory results; otherwise, we risk overestimating their capacity to improve  
688 performance based on animals kept in unrealistic conditions (Hardison and Eliason, 2024).

689  
690 *Larvae escape behavior*

Larval ability to react - evaluated as both the likelihood to react and whether the reaction occurred before or after being touched - was influenced by experimental conditions, whereas reaction time, speed, and meander were not. At the higher rearing temperature (24.5 °C), not all diets were sufficient to maintain an effective escape response in *R. temporaria* larvae. Diets with high protein content and greater representation of animal-derived components, as well as an herbivorous diet, resulted in efficient escape performance. Interestingly, the diet assumed to be of lowest quality produced intermediate results in terms of larval reactivity, whereas larvae receiving intermediate-quality food at 24.5 °C and not exposed to a heat wave exhibited the poorest performance. These results align with observed patterns in larvae niche breadth, suggesting a relationship between nutrient assimilation plasticity (i.e., broader isotopic niches) and escape ability. However, exposure to a heat wave improved the reactivity of larvae reared at 24.5 °C with intermediate-quality food, potentially due to shifts in gut bacterial abundance and activation of metabolic pathways that enhance performance (discussed below).

The use of a complex stimulus combining visual, tactile, and chemical cues may have masked differences in reaction time, as perception and response can vary depending on the cue (Melo et al., 2021). Although testing each cue separately would be informative, we combined them to increase the likelihood that all larvae would perceive and respond to the aversive stimulus. Non-reacting larvae were interpreted as less able to respond to threats, and larvae that waited until being touched were considered less responsive, as contact with a predator in nature would likely result in capture.

*Rana temporaria* larvae develop in small ponds in the Kleiwiesen, where they are exposed to dragonfly naiads but not predatory fish. Higher escape speed is adaptive for larvae facing active predators like fish but not for ambush predators such as Odonata, as phenotypes associated with increased speed are induced by co-occurrence with the former but not the latter (Teplitsky et al., 2005). In this context, the ability to flee promptly upon perceiving a threat likely has a greater impact on survival than escape speed or trajectory in Kleiwiesen larvae (Staudinger et al., 2011).

## *Gut bacteria, predicted metabolic pathways, and their potential influence on larvae performance*

Variations in gut bacterial abundance and predicted metabolic pathways may have contributed to differences in *R. temporaria* larvae performance under the experimental conditions. Escape responses were markedly reduced in larvae reared at 24.5 °C with an intermediate-quality diet and not exposed to a heat wave. In these larvae, *Cloacibacterium* showed increased abundance. Interestingly, *Cloacibacterium* was also abundant in the control group compared to elevated temperatures in rainbow trout (Zhou et al., 2022), although it remains unclear whether this taxon contributed directly to the reduced reactivity in larvae.

In contrast, larvae exposed to a heat wave under the same dietary and rearing temperature conditions showed improved escape performance and a higher abundance of *Klebsiella* (*Enterobacteriaceae*, *Enterobacterales*). This suggests that the heat wave may have

734 triggered proliferation of *Klebsiella*, which in turn could have contributed to enhanced  
735 performance. However, this shift in microbial composition came with a reduction in gut  
736 microbiome diversity, which may reduce host capacity to cope with additional stressors  
737 (Henry et al., 2021).

738 *Klebsiella* may influence host performance through multiple metabolic pathways.  
739 Pathways such as P562-PWY and PWY-7237, involved in myo-inositol and related inositol  
740 derivatives degradation (Berman and Magasanik, 1966a, 1966b; Anderson and Magasanik,  
741 1971; Karp et al., 2019), were relatively increased in treatments with higher temperatures.  
742 Myo-inositol is essential in eukaryotes for membrane phospholipids and cell signaling, and its  
743 metabolism may help maintain membrane fluidity and protein activity - which are influenced  
744 by temperature (Hazel, 1995) - under thermal stress. Additionally, *Klebsiella* may influence  
745 behavior through neuromodulatory signals, as related species (*K. pneumoniae*) affect food  
746 intake and attention in humans via serotonin and dopamine signaling (Miri et al., 2023). Other  
747 upregulated pathways recorded for *Klebsiella*, such as GLUCARDEG-PWY (D-glucarate  
748 degradation) and AEROBACTINSYN-PWY (aerobactin biosynthesis; Karp et al., 2019),  
749 support bacterial growth by enabling carbon use and iron acquisition, which may indirectly  
750 benefit host performance.

751 Other taxa also contributed to larvae performance under specific conditions. *Yersinia*  
752 (*Yersiniaceae, Enterobacteriales*) increased in abundance in larvae reared at low-quality food  
753 and 18 °C under heat wave exposure, although performance did not differ from controls.  
754 *Chryseobacterium*, associated with lipid absorption (Semova et al., 2012), predominated in  
755 larvae fed high-quality food at 18 °C. In larvae fed high-quality food at 24.5 °C, no dominant  
756 biomarkers were detected, yet these individuals developed fastest and exhibited effective  
757 escape responses, likely due to functional redundancy in a diverse microbial community.

758 Predicted metabolic pathways suggest that microbial plasticity may provide alternative  
759 solutions for nutrient acquisition under different temperatures. For example, in larvae reared  
760 at 24.5 °C with low-quality (herbivorous) diets, *Pseudomonas* and *Dysgonomonas* were  
761 abundant in non-heat wave conditions, supporting aerobic aromatic catabolism pathways  
762 (GALLATE-DEGRADATION-I-PWY, GALLATE-DEGRADATION-II-PWY,  
763 METYLGALLATE-DEGRADATION) that enable degradation of plant lignin and tannins  
764 (Karp et al., 2019). At the same time, increased abundance of *Enterobacteriales* under heat  
765 wave exposure likely allowed efficient carbon utilization and maintenance of membrane  
766 function, supporting effective escape responses despite low-quality diets. In the fish  
767 *Plectropomus leopardus* dominant gut bacterial taxa were shown to change within 12 h and  
768 maintain estimated microbial functional capacity constant under different environmental  
769 conditions (Mekuchi et al., 2018).

770 Protein absorption efficiency may decline with increasing temperature in ectotherms  
771 (Croll and Watts, 2004). In fish, low-protein diets lead to gut microbiomes with altered  
772 composition and reduced diversity, which are less efficient at absorbing protein—likely due to  
773 the influence of specific bacterial strains on enterocyte protein uptake (Childers et al., 2025).  
774 For instance, strains of *Acinetobacter*, *Aeromonas*, and *Pseudomonas* can reduce protein  
775 absorption in the fish gut (Childers et al., 2025; Ye et al., 2019). Besides *Pseudomonas*,  
776 *Dysgonomonas* may also be disadvantageous to the host at elevated temperatures. Members

777 of *Bacteroidales* (the order that includes *Dysgonomonas*) use putrescine to produce GABA  
778 (gamma-aminobutyric acid), a molecule that modulates stress responsiveness in humans (Miri  
779 et al., 2023). Thus, increased putrescine degradation may impair stress responses. In our  
780 study, the superpathway of L-arginine, putrescine, and 4-aminobutanoate degradation  
781 (ARGDEG-PWY) was upregulated in larvae reared at 24.5 °C on low-quality food and  
782 exposed to a heat wave. However, these larvae also showed increased abundances of  
783 *Enterobacteriales* (the order that includes *Klebsiella*), which may have facilitated the  
784 degradation of diverse carbon sources from the herbivorous diet and regulated membrane  
785 functions (as discussed above), ultimately allowing larvae to maintain an effective escape  
786 response.

787 Some pathways also suggest potential benefits for coping with environmental  
788 pollutants. PWY-5180 and PWY-5182, corresponding to toluene degradation, were associated  
789 with *Pseudomonas* (Fishman et al., 2004; Karp et al., 2019) and may help larvae survive in  
790 polluted habitats. Additionally, PWY-6629, the L-tryptophan biosynthesis pathway, increased  
791 under higher temperatures. In other ectotherms, dietary L-tryptophan improves growth and  
792 thermic stress resistance (Akthar et al., 2013), suggesting possible similar benefits mediated  
793 by the microbiome, although this pathway has only been documented for *E. coli* due to  
794 limited ectotherm microbiome studies (Legrand et al., 2020; Eterovick et al., 2024).

795 Overall, exposure to elevated temperatures - either long-term or as short-term heat  
796 waves - was associated with increases in the most significant metabolic pathways, though not  
797 uniformly across treatments. This variability aligns with individual differences in  
798 microbiome-host interactions and may underlie observed variation in larvae performance  
799 under different environmental conditions.

800  
801 *Concluding remarks*  
802

803 At a temperature equivalent to that naturally experienced by *R. temporaria* (18 °C), food  
804 quality - defined by high protein, fat, and animal component content - did not appear to be a  
805 decisive factor for larval performance, including developmental rate and the ability to detect  
806 and escape from threats. Under these conditions, the gut bacterial community may have  
807 adjusted to variations in food quality and exposure to short-term heat stress, contributing to  
808 the maintenance of host metabolic functions.

809 However, at elevated rearing temperatures, food quality became a key determinant of  
810 developmental rate and interacted with additional temperature fluctuations, such as heat  
811 waves, shaping both the microbiome and behavioral outcomes. Larvae fed the diet richest in  
812 protein, fat, and animal components developed the fastest and were among the most likely to  
813 respond early to threats. Such traits would increase survival likelihood, allowing these larvae  
814 to leave warming and potentially drying habitats quickly and to escape predators efficiently.  
815 Interestingly, larvae fed a herbivorous diet - low in protein, fat, and component diversity - also  
816 exhibited effective escape responses. These comparable outcomes suggest that alternative  
817 bacterial communities, triggered by environmental conditions, may provide functional  
818 redundancy, supporting host performance despite differences in diet.

819        Larvae receiving intermediate-quality diets, with moderate inclusion of animal  
820 components, showed variable outcomes depending on heat wave exposure. This variability  
821 indicates that a more herbivorous diet may represent a safer strategy in unpredictable  
822 environments where high-quality animal food may not be consistently available. Temperature-  
823 modulated microbial growth may further favor the consumption of specific food types, as  
824 microbes play a key role in nutrient assimilation (Newsome et al., 2011; Vejříková et al.,  
825 2016). Supporting this, studies across diverse ectotherms - from insects to vertebrates - have  
826 often documented increased herbivory under elevated temperatures (Behrens and Lafferty,  
827 2007; Carreira et al., 2016; Brankatschk et al., 2018; Zhang et al., 2020), although exceptions  
828 exist (Trip et al., 2014; Schmitz et al., 2016). To better understand these patterns, future  
829 research should investigate wild ectotherms' microbiomes, isotopic signatures, and health  
830 biomarkers, linking diet composition, microbiome-mediated nutrient assimilation, and host  
831 condition in natural habitats.

832        As human activities increase the intensity and frequency of environmental changes,  
833 accelerating species extinction rates (IPCC, 2023), understanding the role of the microbiome  
834 in animal resilience becomes increasingly important. Microbiomes are dynamic communities  
835 (Louca et al., 2018) that respond to environmental fluctuations (Mekuchi et al., 2018).  
836 Therefore, studies integrating multifactorial interactions among host, microbiome, and  
837 environment, and collecting data from animals under natural conditions, are essential to  
838 accurately interpret laboratory findings and predict ecological outcomes.

1207

1208 **Animal husbandry and experimental setup**

1209 The transport of egg clutches took approximately 30 minutes. Upon arrival, clutches were  
1210 carefully transferred to separate trays containing about 10 L of water from the original habitat  
1211 and equipped with aerators. Larvae hatched on 2 April 2023. Both clutches and newly hatched  
1212 larvae were maintained in a large room with windows along two walls, which were kept open  
1213 to expose the animals as closely as possible to natural light and temperature conditions.

1214 Approximately one third of the water was replaced every two days with fresh water from the  
1215 original habitat. This replacement water was collected every three days and stored at 4 °C in  
1216 buckets. Before use, buckets were placed in the same room as the animals until the water  
1217 reached the same temperature as that in the rearing containers ( $14 \pm 0.2$  °C).

1218 Nine days after hatching, larvae reached developmental stage 25 (*sensu* Gosner, 1960),  
1219 the point at which they deplete yolk reserves and begin feeding independently. At this stage,  
1220 120 larvae were placed individually into 1.2-L buckets containing 1 L of filtered, rested tap  
1221 water and kept under a 14:10 h light:dark cycle. Larvae were randomly assigned to three food  
1222 treatments (Fig. 1). Buckets for the 18 °C treatment were placed in a climate chamber (Kälte-  
1223 Klimatechnik-Frauenstein GmbH, Germany). For the 24.5 °C treatment, buckets were placed  
1224 inside a water bath housed within large plastic boxes (Surplus Systems Eurobox, 60 × 40 × 22  
1225 cm) in a different room, with temperature regulated by two adjustable heating elements (JBL  
1226 PROTEMP S 25, 25 W, JBL GmbH & Co. KG, Germany). Water temperature in the buckets  
1227 was gradually increased at a rate of 0.5 °C per hour until the target temperature was reached.

1228 Diet quality was classified based on component diversity, protein and fat levels, and  
1229 caloric content. The organic grass powder contains only one plant species and has lower  
1230 caloric, protein, and fat content, whereas the fish food contains a wide range of ingredients  
1231 (algae, zooplankton, plant and animal products) and is higher in calories, protein, and fat.

1232 The powders used in all three diets have similar texture and solubility. They remain  
1233 suspended in water for a short time before settling, ensuring that the feeding mechanisms of  
1234 frog larvae - filtering and scraping surfaces - provide equal access to both powders when  
1235 mixed at a 50:50 ratio. All diets were provided *ad libitum*. Buckets were cleaned at least every  
1236 three days by completely replacing the water with rested tap water at the same temperature,  
1237 during which each larva was briefly (<1 min) transferred to a sieve placed in a separate bucket  
1238 of clean water.

1239 Buckets assigned to the heat-wave treatment were placed in a water bath inside plastic  
1240 boxes (60 × 40 × 22 cm) containing two adjustable heating elements. The setup was housed in  
1241 a warmer room (29 °C air temperature). Prior to the experiment, the heating system was  
1242 calibrated to ensure accurate temperature ramping, and water temperatures were monitored  
1243 hourly. Water temperature in the buckets was increased at a rate of 0.5 °C per hour until  
1244 reaching 28 °C. Because ramping protocols were identical and final temperatures (i.e.,  
1245 original rearing temperatures) differed, larvae reared at 18 °C required more time to reach 28  
1246 °C and return (20 h total) than larvae reared at 24.5 °C (7 h total). Buckets assigned to the

1247 control treatment (no heat wave) were also moved and returned to their original positions  
1248 during treatment allocation so that handling was standardized across experimental groups.

1249

## 1250 **Methods for isotope analyses**

1251 Larval tails were dried in an oven at 60 °C for at least 24 hours. Subsequently, tail muscle  
1252 tissue samples weighing 0.38-0.93 mg (mean = 0.76 mg) were taken in duplicate for each  
1253 larva and placed in 4 × 6 mm tin cups (HEKAttech, Germany). The powdered foods  
1254 corresponding to the three dietary treatments (NaturaleBio® grass powder, Sera Micron  
1255 Nature® fish food, and a 50:50 mixture of both) were also analyzed, with six replicates per  
1256 diet.

1257 Samples were combusted in a mass spectrometer (EURO-EA 3000, Euro Vector, Italy)  
1258 using BBOT (2,5-Bis-(5-tert-butyl-2-benzoxazolyl)-thiophen; 6.51% N; 72.52% C;  
1259 HEKAttech, Germany), KNO<sub>3</sub>, and caffeine as standards. Isotope ratios are reported in  $\delta$   
1260 notation (‰) relative to atmospheric nitrogen (AIR) for  $\delta^{15}\text{N}$  and Pee Dee Belemnite (PDB)  
1261 for  $\delta^{13}\text{C}$ , following international reference standards (Fry, 2006).

1262

## 1263 **Sequence quality filtering, sample depth, and taxonomic assignment**

1264 Paired-end demultiplexed FASTQ files were imported into QIIME2 and denoised using  
1265 the q2-deblur algorithm, which applies quality filtering based on Bokulich et al. (2013),  
1266 associates erroneous sequences with their true biological sequences, and removes chimeras.  
1267 Forward and reverse reads were paired, quality filtered, and trimmed to a high-quality length  
1268 (median Illumina Q30), resulting in 250 bp sequences. Of the initial 2,737,481 reads, 148,401  
1269 remained after filtering, with sequencing depths between 207 and 5,451 reads per sample. All  
1270 negative controls (five extraction and two PCR controls) yielded zero reads after filtering.

1271 A phylogenetic tree was constructed using the Greengenes 16S rRNA backbone tree  
1272 (version gg-13-8; McDonald et al., 2012). Taxonomic classification was performed using a  
1273 custom-trained classifier built with reference sequences, taxonomy, and animal proximal gut-  
1274 specific sequence weights (SILVA release 138.1, 515F/806R) from Kaehler et al. (2019;  
1275 <https://github.com/BenKaehler/readytowear>). Positive controls were evaluated separately via  
1276 BLAST (NCBI; Sayers et al., 2025) because they do not represent animal gut samples.

1277 Amplicon Sequence Variants (ASVs) represented by fewer than eight reads (~0.005% of  
1278 total remaining sequences) were removed to minimize artifacts from amplification errors  
1279 (Bokulich et al., 2013). The remaining reads were used to calculate Shannon entropy, which  
1280 reached saturation at 556 reads. Samples with fewer than 556 reads (15 samples, one to three  
1281 per treatment) were excluded from further analyses.

1421 Fig. S22. Relationship between body condition (SMI) of *Rana temporaria* larvae and  
 1422 trajectory non-linearity (“meander”, log transformed) while fleeing from the aversive stimulus  
 1423 presented in behavioral trials. Adjusted R-squared = -0.009, F = 0.247, df = 79, p = 0.620.

1424

1425 Fig. S23. Relationship between number of attempts to position *Rana temporaria* larvae before  
 1426 the start of the behavioral trials and trajectory non-linearity (“meander”, log transformed) of  
 1427 the larvae while fleeing from the aversive stimulus presented.  $\rho = 0.050$ ,  $p = 0.657$ .

1428

1429

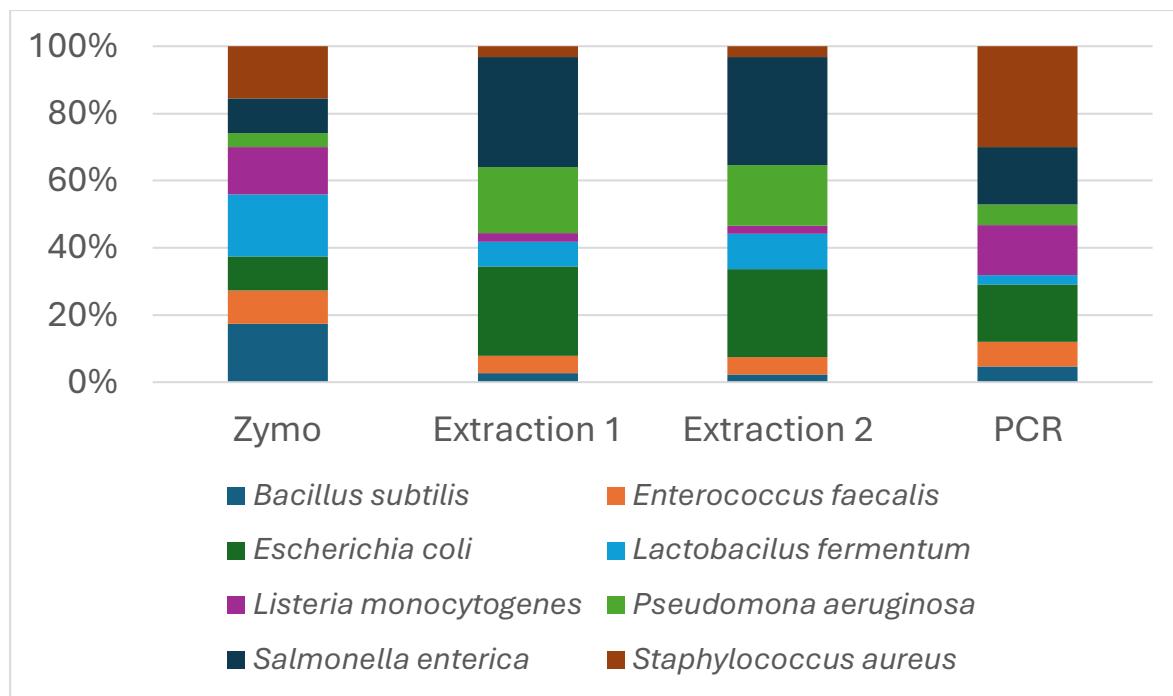

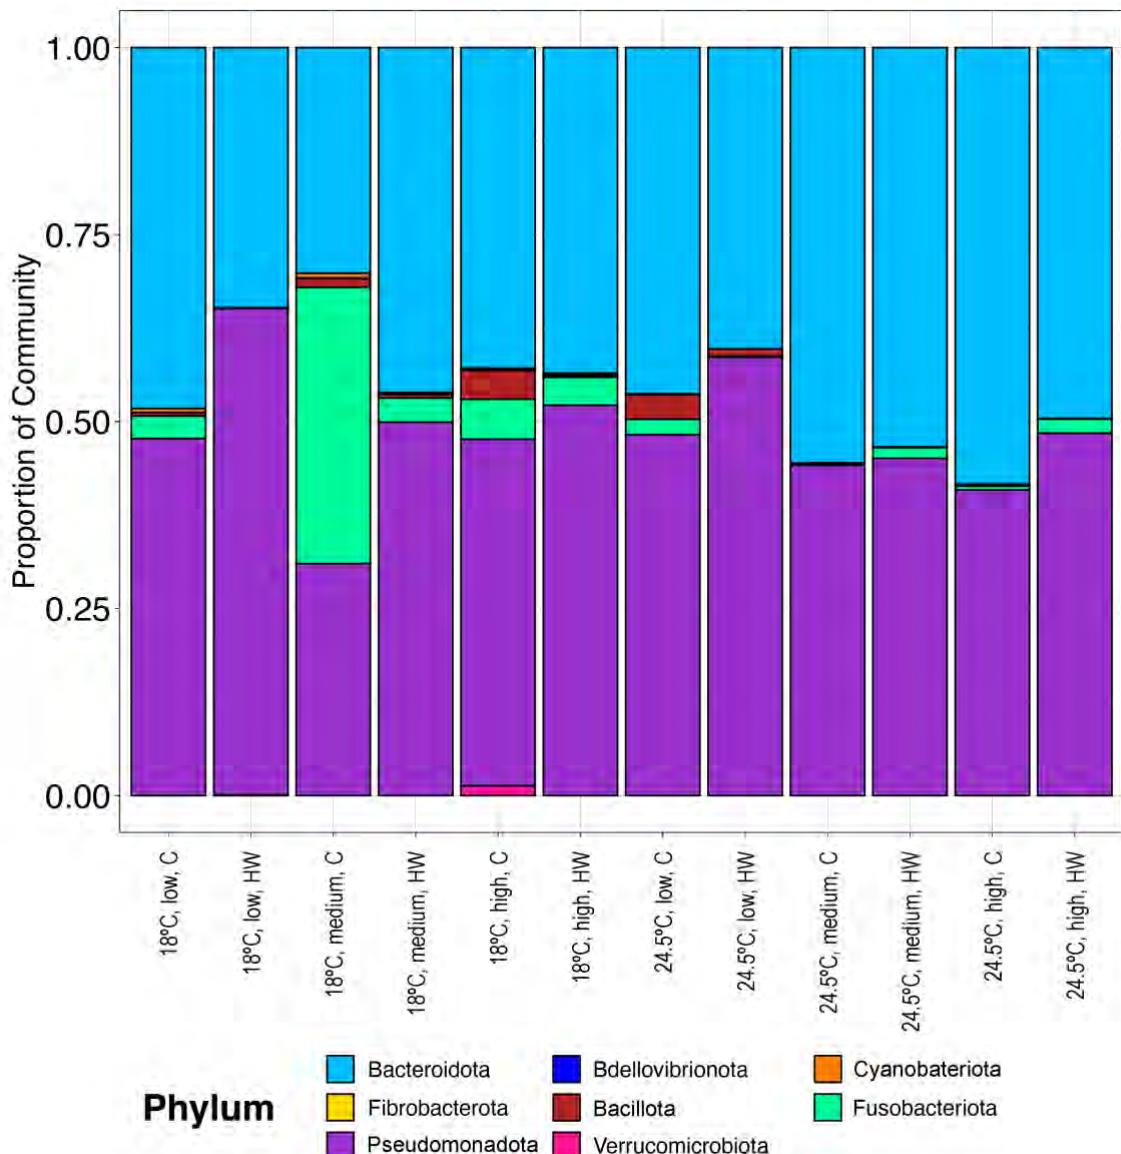

Fig. S24. Results of two positive controls for DNA extractions (ZymoBIOMICS™ microbial community standard, Zymo Research Europe GmbH) and one positive PCR control (ZymoBIOMICS™ microbial community DNA standard, Zymo Research Europe GmbH) in comparison with the expected community profile (Zymo), showing that taxonomic composition was precisely assessed, but not relative abundances. The similarity of the two extractions shows repeatability, meaning that bias in reflecting the real abundance of given taxa are consistent and, thus, comparable among samples.

1440

1441 Fig. S25. Community composition of gut bacteria based on phylum for *Rana temporaria*  
 1442 larvae fed three diets with increasing levels of protein, fat, and animal components  
 1443 (considered as low-, medium- and high-quality), reared at either 18 °C or 24.5 °C. and  
 1444 exposed or not to a heat wave, in a crossed experimental design. The heat wave corresponded  
 1445 to increasing temperature at a ramping rate of 0.5 °C per hour until 28 °C, maintenance at 28  
 1446 °C for 48 h and subsequent temperature decrease of 0.5 °C per hour until original rearing  
 1447 temperature.

Table S1. Permanova pairwise comparisons among treatments applied to *Rana temporaria* larvae based on unweighted unifrac distances. Treatments corresponded to three diets with increasing levels of protein, fat, and animal components (considered as low-, medium- and high-quality), two rearing temperatures (18 °C or 24.5 °C), and exposed or not (C = control) to a heat wave (HW).
