## Abstract

Cheating is an ubiquitous evolutionary strategy, appearing everywhere throughout the tree of life. Among bacteria, cheating appears mostly through the consumption of public good without participation in their production. Some vaccines, because they specifically target these public goods, may alter the eco-evolutionary dynamics of cheating in bacterial populations of pathogenic species such as *Corynebacterium diphtheriae*, the etiological agent of diphtheria, which produces a public virulence factor. We expand a series of fitness models to assess how the use of vaccines targeting a public good can impact the selective value of its production, alter the ecological dynamics between producers and non-producers, and select for novel phenotypes. Our results show that producers are counter-selected when a vaccine is used but only when the public good is non-mandatory for the growth and survival of the bacteria, and that the presence of non-producers facilitates the eradication of producers. These results advocate for comprehensive studies of the eco-evolutionary consequences of vaccines and illustrate how the competition between non-producers and producers can be useful in the eradication of public virulence factors producers.

## 1 Introduction

2 In ecology and evolutionary biology, cheating  
3 can be defined as “a trait that is beneficial to a  
4 cheat[er] and costly to a cooperator in terms of  
5 inclusive fitness” (Ghoul et al., 2014). This type of  
6 behavior is widespread along the tree of life and  
7 can emerge at different ecological scales. For ex-  
8 ample, it has been described between individuals  
9 of the same species and sex, such as lekking male  
10 frogs satelliting more competitive males (Castel-  
11 lano et al., 2009) between individuals of the same  
12 species but opposite sex, such as male spiders  
13 deceiving their mates with worthless nuptial gifts  
14 (Beydizada et al., 2025) and between individuals  
15 of different species, such as cleaner fishes cheat-  
16 ing on their clients by feeding on their tissues  
17 (Wilson et al., 2014) or non-rewarding female  
18 flowers deceiving pollinators by mimicking re-  
19 warding male flowers (Castillo et al., 2012).

20 Cheating necessarily emerges from cooperative  
21 behaviors: in the examples above, lekking frogs  
22 gather in a chorus to simplify the mating  
23 process for every participating male, male spiders

exchange food with a copulation opportunity, 24  
cleaner fishes feed on ectoparasites of larger 25  
fishes, and pollinators help flowers reproduce 26  
while feeding on them. By nature, cheating can 27  
thus be differentiated from other interactions 28  
such as predation, competition or parasitism 29  
(even though intraspecific cheating is sometimes 30  
referred to as “intraspecific parasitism”). Cheat- 31  
ing has long been questioned in the field of 32  
evolutionary biology as an obstacle to the main- 33  
tenance of cooperative behaviors, while cooper- 34  
ative behaviors themselves have been questioned 35  
in the global “selfish-gene” framework (West et 36  
al., 2007). 37

Ghoul et al. (2014) define two families of cheating 38  
behavior: interception and manipulation, which 39  
we could also refer to as passive and active 40  
cheating, respectively. In interception cheating, 41  
individuals “hijack” cooperative products or be- 42  
haviors, while in manipulation cheating cheaters 43  
actively exploit cooperative behaviors (for exam- 44  
ple, by mimicking them) to ensure a gain in 45  
fitness at the expense of truly cooperative indi- 46

47	viduals. In the examples given above, the behavior of the satellite male frogs would fit within the definition of interception while other behaviors would be classified as manipulation.	95

50		
51	Interception is particularly well represented in the domain of bacteria. Many bacterial species or populations produce public goods, i.e., costly molecules which can be beneficial to other cells in the neighborhood of the producer. By nature, production of a public good is a cooperative behavior: all individuals (should) participate in the production of the good and take a part of the common benefit. One of the most studied example of a bacterial public good might be pyoverdine, a siderophore produced by species of the <i>Pseudomonas</i> genus (Ghssein & Ezzeddine, 2022). Pyoverdine is mandatory for iron acquisition in multiple environments, and its production is modulated by the availability of iron (Ghssein & Ezzeddine, 2022). There are thus high stakes linked with the production of this molecule and, more broadly, with the production of siderophores. Because of the “public good” property of siderophores, it has been both theorized (Bruce et al., 2017; Lecorvaisier et al., 2024) and shown experimentally (Butaité et al., 2017) that cheaters should and indeed do emerge in siderophore-producing populations of <i>Pseudomonas</i> , <i>Corynebacterium diphtheriae</i> and other genuses and species.	98

77	Cheating bacteria that do not produce siderophores can appear in a variety of contexts. In the pathogenic species <i>P. aeruginosa</i> , it has been shown that pyoverdine non-producers emerge during lung infections. These non-producers can be classified as cheaters as they maintain the capacity to exploit the pyoverdine produced by cooperative cells. Moreover, it has been shown that the proportion of non-producers increases with time and that the capacity of cheaters to take up the pyoverdine is maintained only until cooperators disappear from the population (Andersen et al., 2015). In natural communities of pseudomonads, it has been shown that the relationship between producers and non-producers is complex, with non-producers developing strategies to exploit the siderophores produced by cooperators, and producers developing	123

	strategies to repress cheating behaviors, much like what the Red Queen hypothesis describes (Bruce et al., 2017; Butaité et al., 2017).	95
		96
		97
	As any evolutionary strategy, cheating is complex. On one hand, and as exemplified above with pyoverdine cheaters, it may emerge or disappear due to changes in the environment (e.g., change in resources, in population density...) and may not always be expected or predictable (Ghoul et al., 2014). On the other hand, we live in an ever-changing world where global warming, globalization, antibiotics... create new environments and life conditions for millions of species. All these phenomena may have an impact on the evolution of cheating as a behavior and cheaters as a population. In the present study, we focus on one global change: vaccination. Vaccines against many diseases became widespread during the second half of the 20 <sup>th</sup> century and lead to evolutionary consequences such as the emergence of vaccine-escape strains of the hepatitis B virus (Santos et al., 2017; Wang et al., 2017), the emergence of hypervirulent strains of the Marek’s disease virus (Gimeno, 2008), and multiple important changes in the genotype and phenotype of circulating strains of <i>Bordetella pertussis</i> , the etiological agent of whooping cough (Lefrancq et al., 2022).	98

	We hypothesize that vaccines specifically targeting public goods, such as modern diphtheria vaccines, should alter the dynamics between cooperator and cheater phenotypes. To investigate this hypothesis, we expand a theoretical model of competition between strains of a bacterium producing a public good. Understanding how vaccination may alter this competition is of great importance as public goods can also be virulence factors or linked to virulence factors, as are the diphtheria toxin of <i>C. diphtheriae</i> (Tiwari & Wharton, 2012) or the pyoverdine of <i>P. aeruginosa</i> (Buckling et al., 2007).	123

	<b>Model &amp; Results</b>	136
	Bruce et al. (2017) proposed a mathematical model describing the competition dynamics between two types of cells (or phenotypes) in a population of bacteria. The first type is called “cooperator cell”, named like this because it pro-	137
		138
		139
		140
		141

142 duces a public good necessary for the growth of  
 143 any cell of the population. The second type is  
 144 called “cheater cell” because it does not produce  
 145 the public good but is able to use the good pro-  
 146 duced by cooperator cells. Their model defines  
 147 the fitness of the cell as a function of the ener-  
 148 getic cost of producing the good,  $q$ , among other  
 149 parameters. If costly, producing the public good  
 150 is also beneficial to the cell, as it is mandatory for  
 151 the reproduction and survival of the cell.

152 This model describes the ecology and evolution  
 153 of an environmental bacteria, *Pseudomonas fluo-*  
 154 *rescens*, but it can be applied to other biological  
 155 systems. In the present work, we generalize the  
 156 model developed by Bruce et al. (2017) while sim-  
 157 plifying some aspects, and apply its study to the  
 158 case of pathogenic bacteria with different pheno-  
 159 types, noted  $i$  and considered here through the  
 160 variability in the production of the public good.

161 The fitness of any  $i$ -phenotype cell can be ex-  
 162 pressed as

$$W_i = C_i (B_i + B_j)^\alpha, \quad (1)$$

163 where  $C_i$  is the cost of producing goods (public  
 164 or private) for cell  $i$  and  $(B_i + B_j)^\alpha$  is the ben-  
 165 efit for cell  $i$ ,  $\alpha$  being a shape parameter. The  
 166 benefit is divided in two parts: the benefit linked  
 167 to the individual production of the  $i$ -phenotype  
 168 cell production ( $B_i$ ) and the benefit linked to the  
 169 public good production from other cells, from the  
 170 same or different phenotype ( $B_j$ ).

171 The cost of the good production is

$$C_i = 1 - q_i - g, \quad (2)$$

172 where  $0 \leq q_i < 1$  is the production of the public  
 173 good for an  $i$ -phenotype cell and  $0 \leq g < 1$  is the  
 174 production of other (private) goods, considered  
 175 equal among cells. We consider that  $q_i + g < 1$   
 176 to avoid the cost of producing the different goods  
 177 to reach one.

178 The benefit for an  $i$ -phenotype cell derived from  
 179 its own production is

$$B_i = (1 - \lambda)(1 - \eta)q_i + g, \quad (3)$$

180 where  $\lambda$  is the fraction of the public good pro-  
 181 duction that is shared with other cells in the

182 population and  $\eta$  is the efficacy of an (imperfect) 182  
 183 vaccine targeting the public good. If  $\lambda = 0$  then 183  
 184 the good is not shared at all and that it is in reality 184  
 185 a private good. Thus, we posit  $\lambda > 0$ . 185

186 The benefit for an  $i$ -phenotype cell derived from 186  
 187 the production of other cells is 187

$$B_j = \lambda(1 - \eta) \sum_j x_j q_j \quad (4)$$

188 where  $x_j$  is the fraction of  $j$ -type cells in the 188  
 189 population and  $q_j$  is the good production by  $j$  189  
 190 -phenotype cells (including other  $i$ -phenotype 190  
 191 cells). In the following of this work, we will call 191  
 192  $B_i$  the “private benefit” and  $B_j$  the “public ben- 192  
 193 efit”. 193

194 There are three main differences between this 194  
 195 model and the one proposed by Bruce et al. 195  
 196 (2017). The first one is that their model takes into 196  
 197 account a degree of variability in the ability of 197  
 198 cells to exploit public goods produced by other 198  
 199 cells, which we neglect here. The second one is 199  
 200 that their model considers the public good to 200  
 201 be essential for the fitness of the cells, while in 201  
 202 our model the fitness of an  $i$ -phenotype cell can 202  
 203 be positive as long as  $g > 0$  and  $1 - q_i - g > 0$ . 203  
 204 Finally, the third and most important difference 204  
 205 is that our model considers the use of a vaccine 205  
 206 targeting the public good. 206

207 Equation 1 can be modified to illustrate a variety 207  
 208 of ecological situations with different degrees of 208  
 209 complexity and biological realism. The simplest 209  
 210 situation is to consider an homogeneous popula- 210  
 211 tion where all cells are of the same type ( $j = i$ ) 211  
 212 and thus share the same cost of producing the 212  
 213 public good ( $q_i = q_j = q_1$ ). In this case, each cell 213  
 214 has the same fitness, independent of the fraction 214  
 215 of the public good shared with other cells ( $\lambda$ ). 215

216 This fitness is 216

$$W_1 = C_1 (B_i + B_j)^\alpha, \quad (5)$$

217 where  $C_1 = 1 - q_1 - g$  and  $B_i + B_j = (1 - 217  
 218 \eta)q_1 + g$ . 218

219 We observe that the higher the vaccine efficacy, 219  
 220 the lower the fitness of the cells (Figure 1). This 220  
 221 is easily explained considering that the vaccine 221  
 222 removes the benefit of producing the public good 222

Figure 1: Fitness of the cell type 1 ( $W_1$ ) as a function of public good production ( $q_1$ ) for different values of vaccine efficacy ( $\eta$ ), private good production ( $g$ ) and shape parameter ( $\alpha$ ). The dashed lines indicate the lowest natural boundary for  $W_1$ .

223 without diminishing the cost of production. In-  
 224 terestingly, we observe that, except when  $\eta = 1$   
 225 and it is linear, the relation between the fitness,  
 226  $W_1$  and the production of the public cost,  $q_1$ ,  
 227 follows a concave curve. This means that there  
 228 exists an intermediate optimal value for the  
 229 production of the public good that graphically  
 230 appears to depend on the values of  $\alpha$ ,  $g$  and  $\eta$ .

231 Let  $q_1^*$  be the optimal production of the public  
 232 good, i.e., the value of  $q_1$  maximizing the fitness  
 233 of the cells in this scenario. In a first, naive  
 234 interpretation, this value could be thought as the  
 235 one eventually reached by the clonal population  
 236 because of natural selection (but see infra). It can  
 237 be expressed as

$$q_1^* = \frac{\alpha}{\alpha + 1} - g \frac{\alpha(1 - \eta) + 1}{(1 - \eta)(\alpha + 1)}. \quad (6)$$

238 Equation 6 confirms the graphical observation  
 239 from Figure 1 that the optimal public good pro-  
 240 duction depends on the vaccine efficacy,  $\eta$ , the  
 241 production of the private good,  $g$ , and the shape  
 242 parameter,  $\alpha$ . When  $\eta = 1$ , the second denomi-  
 243 ator in Equation 6 goes to zero. This corresponds

244 to a situation in which the vaccine is perfect and  
 245 the benefit from producing the public good is  
 246 removed from Equation 5.

247 We observe in Equation 6 that it is possible that  
 248  $q_1^* < 0$ . Indeed, the left term is always lower than  
 249 one because  $\alpha > 0$  and the right term is always  
 250 positive because  $0 \leq g \leq 1$  and  $0 \leq \eta \leq 1$ ; and  
 251 the right term converges toward infinity when  $\eta$   
 252 converges toward one. This implies that produc-  
 253 tion of the public good can be counter-selected  
 254 under certain circumstances.

255 This is graphically confirmed in Figure 2, hinting  
 256 to the existence of a vaccine efficacy threshold  
 257 above which counter-selection occurs. Figure 2  
 258 also shows that the vaccine efficacy only impacts  
 259 the optimal public good production when there  
 260 is some form of private good production (i.e.,  $g \neq$   
 261 0).

262 Let  $\eta'_1$  be the vaccine efficacy threshold above  
 263 which the production of the public good should  
 264 be counter-selected, i.e., the value such that  
 265  $q_1^*(\eta = \eta'_1) = 0$ . This value is

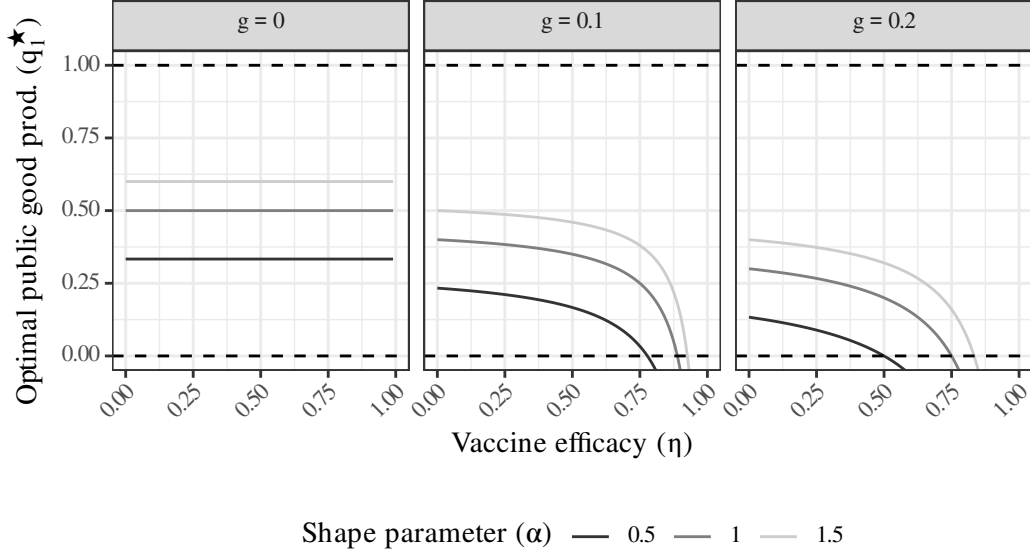

Figure 2: Optimal public good production ( $q_1^*$ ) as a function of vaccine efficacy ( $\eta$ ) for different values of shape parameter ( $\alpha$ ) and private good production ( $g$ ). The dashed lines indicate the natural boundaries of  $q_1^*$ .

$$\eta'_1 = 1 - \frac{g}{\alpha(1-g)}, \quad (7)$$

266 and we can show that for all  $\eta > \eta'_1$ ,  $q_1^* < 0$ .  
 267 This finding is particularly interesting because  
 268 it shows that the private good production plays  
 269 an important role on the value of this vaccine  
 270 efficacy threshold. We observe that the higher the  
 271 private good production, the lowest the vaccine  
 272 efficacy threshold (Figure 3).

273 Interestingly, we can also observe a certain  
 274 threshold in the private good production beyond  
 275 which the production of the public good is  
 276 counter-selected whatever the vaccine efficacy  
 277 (i.e.,  $\eta'_1 \leq 0$ ). This threshold is

$$g'_1 = \frac{\alpha}{\alpha + 1}. \quad (8)$$

278 Until now, we considered the simplest possible  
 279 model where the population was composed of

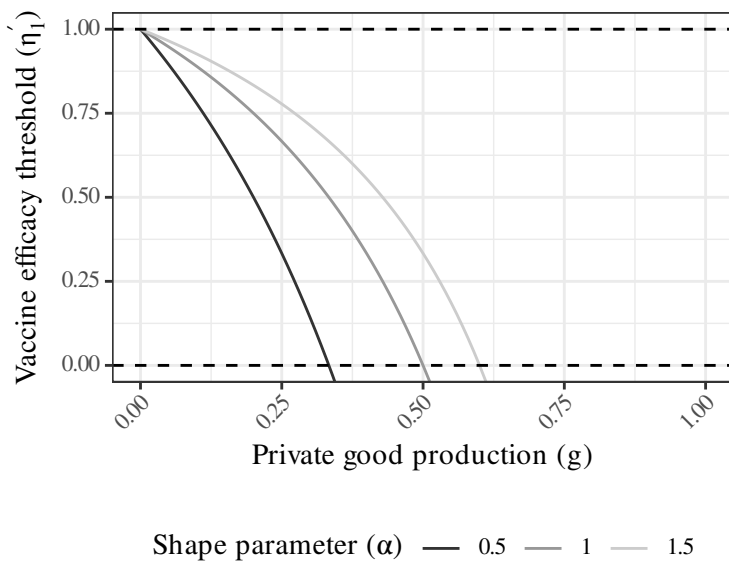

Figure 3: Vaccine efficacy threshold ( $\eta'_1$ ) as a function of private good production ( $g$ ) for different values of the shape parameter ( $\alpha$ ). The dashed lines indicate the natural boundaries of  $\eta'_1$ .

280 clonal cells. In the following part, we consider  
 281 a dimorphic population. The first phenotype,  
 282 which we call “cooperator” or 2.1-type, produces  
 283 the public good with a level  $q_{2.1} > 0$ . The second  
 284 phenotype, which we call “cheater” or 2.2-type,  
 285 does not produce the public good ( $q_{2.2} = 0$ ) but,  
 286 as hinted in Equation 1, it can profit from public  
 287 goods produced by cooperator cells. The fitness  
 288 of the cooperator phenotype is

$$W_{2.1} = C_{2.1}(B_{2.1} + B_j)^\alpha, \quad (9)$$

289 and the fitness of the cheater phenotype is

$$W_{2.2} = C_{2.2}(B_{2.2} + B_j)^\alpha. \quad (10)$$

290 The cost for any cooperator cell is

$$C_{2.1} = 1 - q_{2.1} - g, \quad (11)$$

291 while the cost for any cheater cell is

$$C_{2.2} = 1 - g. \quad (12)$$

292 Thus, because  $q_{2.1} > 0$ , we know that  $C_{2.2} <$   
 293  $C_{2.1}$ , meaning that cheater cells have a lower cost  
 294 than cooperator cells.

295 On the other hand, each cooperator cell has a  
 296 personal benefit

$$B_{2.1} = (1 - \lambda)(1 - \eta)q_{2.1} + g, \quad (13)$$

297 and each cheater cell has a personal benefit

$$B_{2.2} = g, \quad (14)$$

298 while each cell in the population has a public  
 299 benefit

$$B_j = \lambda(1 - \eta)x_{2.1}q_{2.1}. \quad (15)$$

300 where  $x_{2.1}$  is the proportion of cooperator cells in  
 301 the population. We note that, as stated earlier and  
 302 contrarily to the original model by Bruce et al.  
 303 (2017), cheater cells can have a positive fitness in  
 304 the absence of cooperator cells (i.e., when  $x_{2.1} =$   
 305  $0$ ) as long as the production of the private good  
 306 is not null (i.e.,  $g > 0$ ).

307 Depending on the parameters values, and be-  
 308 cause the proportion of cooperator cells is by  
 309 nature not static, different outcomes may emerge  
 310 for this scenario. It is possible that the fitness of  
 311 the cooperator phenotype exceed the fitness of

the cheater phenotype whatever the proportion 312  
 of cooperator cells (e.g., Figure 4, top-left panel). 313  
 In this case, the proportion of cooperator cells 314  
 should gradually increase, leading the cheater 315  
 phenotype to extinction (Figure 5). Another possi- 316  
 ble outcome is the fitness of the cheater phe- 317  
 notype exceeding the fitness of the cooperator 318  
 phenotype whatever the proportion of coopera- 319  
 tor cells (e.g., Figure 4, bottom-left panel). In this 320  
 case, the proportion of cooperator cells should 321  
 gradually decrease, leading the cooperator phe- 322  
 notype to extinction (Figure 5). Finally, in the 323  
 third possible outcome, the fitness of the cooper- 324  
 ator phenotype may be higher or lower than the 325  
 fitness of the cheater phenotype depending on 326  
 the proportion of cooperator cells (e.g., Figure 4, 327  
 middle-left panel). In this case, the proportion of 328  
 cooperator cells should converge toward a value 329  
 where  $W_{2.1} = W_{2.2}$  and both phenotypes should 330  
 coexist (Figure 5). 331

This phenomenon emerges because of the nature 332  
 of the interaction of the two different pheno- 333  
 types. Equation 9 and Equation 10 show that the 334  
 fitness of both phenotypes increases along with 335  
 the relative prevalence of cooperator cells,  $x_{2.1}$ . 336  
 Moreover, because it does not bear any cost of 337  
 public good production, the fitness of cheater 338  
 cells,  $W_{2.2}$ , increases faster than the fitness of 339  
 cooperator cells,  $W_{2.1}$ , when  $x_{2.1}$  increases (Fig- 340  
 ure 4, all panels). However, if  $W_{2.2} > W_{2.1}$ , then 341  
 the relative prevalence of cooperator cells should 342  
 decrease because of the competitive advantage 343  
 of cheater cells, leading to a decrease in the 344  
 fitness of the cheater phenotype. Therefore, as 345  
 stated above, the proportion of cooperator cells 346  
 should converge toward an optimal, stable value 347  
 for which  $W_{2.1} = W_{2.2}$ . This value is given in 348  
 Equation 16. 349

We observe that the numerator of Equation 16 350  
 can fall below zero, which would result in  $x_{2.1}^*$  351  
 to also fall below zero. This outcome corresponds 352  
 to the situation exposed earlier where the coop- 353  
 erator phenotype goes extinct. We observe that 354  
 the denominator is zero if  $\eta = 1$  or  $q_{2.1} = 0$ . In 355  
 these situations, the production is either null or 356  
 nullified by the vaccine, leading automatically 357  
 the cooperator phenotype to extinction, and  $x_{2.1}^*$  358  
 does not exist. 359

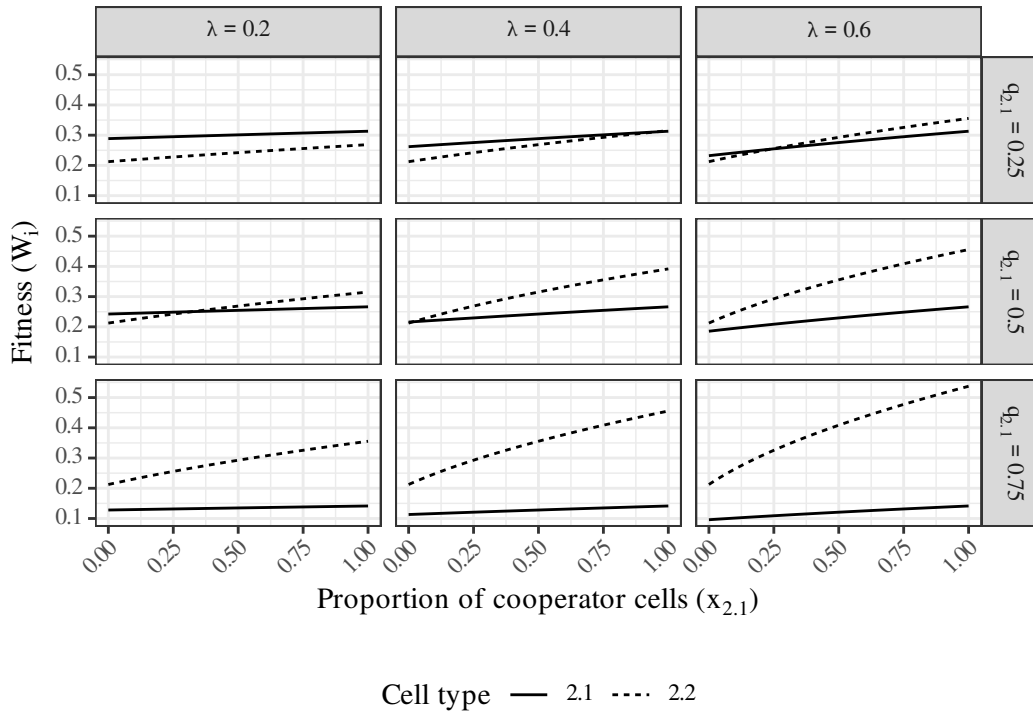

Figure 4: Fitness of the cell types 2.1 ( $W_{2,1}$ ) and 2.2 ( $W_{2,2}$ ) as a function of the proportion of cooperator cells ( $x_{2,1}$ ) for different values of the fraction of the public good that is shared ( $\lambda$ ) and public good production ( $q_{2,1}$ ). Other parameter values are  $\alpha = 0.5$ ,  $\eta = 0.4$  and  $g = 0.05$ .

360 In the special case where  $g = 0$  (i.e., the fitness is completely conditioned by the production of the public good) we can notice that it is not theoretically possible for the cooperator phenotype

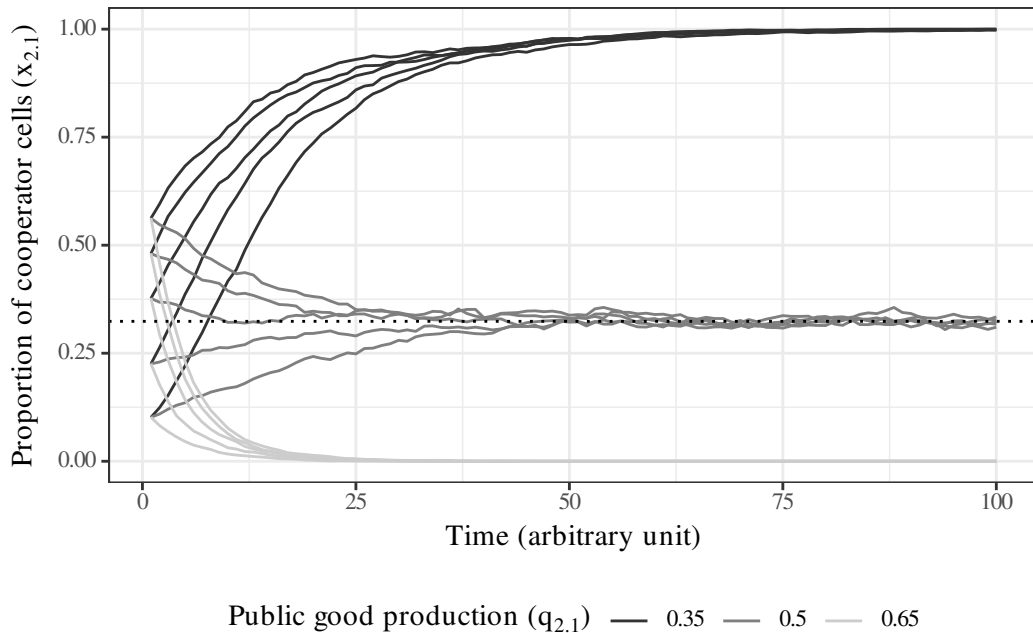

Figure 5: Change in the proportion of cooperator cells ( $x_{2,1}$ ) with time for different values of public good production ( $q_{2,1}$ ). Other parameters values are  $\alpha = 0.5$ ,  $\eta = 0.4$ ,  $g = 0.05$  and  $\lambda = 0.2$ . The dotted line indicates the converging value of  $x_{2,1}$  for  $q_{2,1} = 0.5$  according to Equation 16. For details on the simulator, see the Supplementary material.

364 to go extinct because of competitive pressure,  
 365 except if  $\lambda = 1$  (the public good is completely  
 366 shared), or in one of the two situations described  
 367 above:  $\eta = 1$  (the vaccine “perfectly” blocks the  
 368 fitness) or  $q_{2,1} = 0$  (no public good is produced).  
 369 Note that in any of these three possible cases  
 370 the cheater phenotype should go extinct as well  
 371 since its fitness relies entirely on the existence  
 372 of the cooperator phenotype when  $g = 0$ . Recip-  
 373 rocally, it is possible that the numerator exceeds  
 374 the denominator, which would result in  $x_{2,1}^*$  to  
 375 go beyond one. This outcome corresponds to  
 376 the situation where the cheater phenotype goes  
 377 extinct.

378 Globally, we can observe that the proportion of  
 379 cooperator cells decreases when the production  
 380 of the public good increases, even when there is  
 381 no production of a private good (Figure 6). It also

382 appears that the larger the fraction of the public  
 383 good that is shared among the population, the  
 384 easier it is for the cooperator phenotype to be  
 385 maintained (Figure 6, columns); and the higher  
 386 the vaccine efficacy, the easier it is for the coop-  
 387 erator phenotype to go extinct (Figure 6, rows).  
 388 Also, we observe that the higher the private good  
 389 production, the lowest the optimal proportion of  
 390 cooperator cells (Figure 6, colors).

391 As we did for the first model, it is interesting to  
 392 investigate the vaccine efficacy threshold, i.e., the  
 393 value of  $\eta$  such that the cooperator phenotype  
 394 should go extinct. We consider that  $x_{2,1}$  fluctu-  
 395 ates way faster than  $q_{2,1}$  (because, in our model, a  
 396 change in  $q_{2,1}$  implies a mutation, while a change  
 397 in  $x_{2,1}$  does not). Thus, we will consider the vac-  
 398 cine efficacy threshold as the value of  $\eta$  for which  
 399  $x_{2,1}^* = 0$ . This value, which we call  $\eta'_{2,1}$ , is given

$$x_{2,1}^* = \frac{(1 - q_{2,1} - g)^{\frac{1}{\alpha}}((1 - \lambda)(1 - \eta)q_{2,1} + g) - (1 - g)^{\frac{1}{\alpha}}g}{\lambda(1 - \eta)\left((1 - g)^{\frac{1}{\alpha}} - (1 - q_{2,1} - g)^{\frac{1}{\alpha}}\right)q_{2,1}} \quad (16)$$

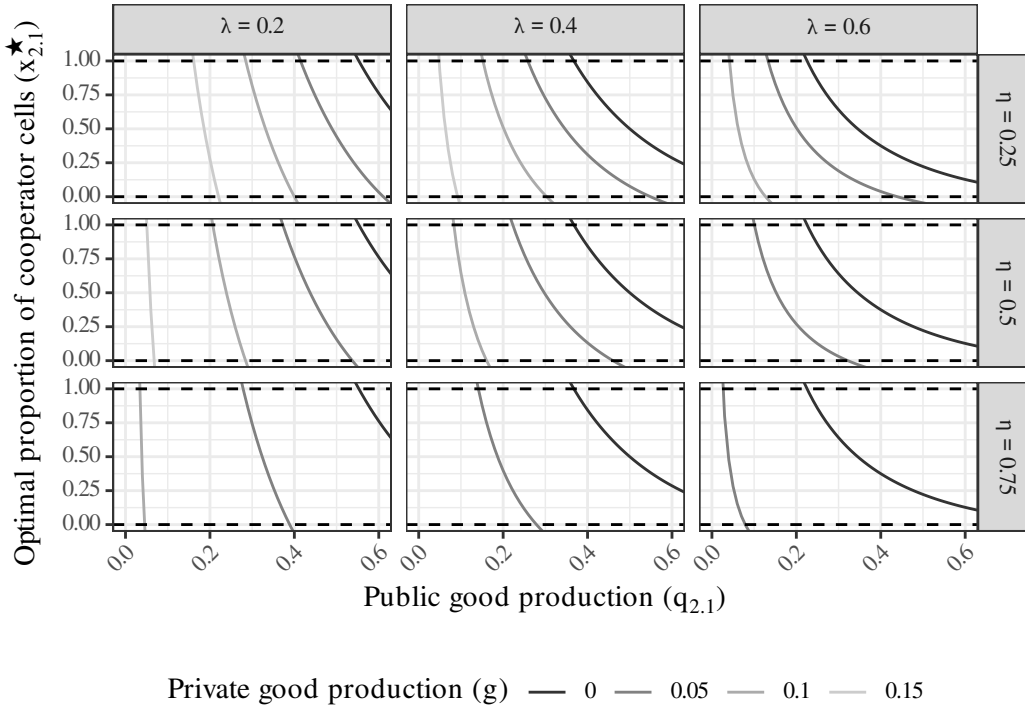

Figure 6: Optimal proportion of cooperator cells ( $x_{2,1}^*$ ) as a function of the public good production ( $q_{2,1}$ ) for different values of the private good production ( $g$ ), fraction of the good that is shared ( $\lambda$ ) and vaccine efficacy ( $\eta$ ). The shape parameter value is  $\alpha = 0.5$ . The dashed lines indicate the natural boundaries of  $x_{2,1}^*$ .

400 in Equation 17. In this formula, the denominator  
 401 goes to zero if  $q_{2,1} = 0$  or  $\lambda = 1$ . The first situ-  
 402 ation implies that no public good is produced,  
 403 and thus  $\eta'_{2,1}$  does not exist. The second situation  
 404 implies that the good is perfectly public. In this  
 405 case, the production of the public good is always  
 406 counter-selected and  $\eta'_{2,1}$  does not exist either.

407 We observe that the vaccine efficacy threshold  
 408 decreases when the public good production  
 409 increases, showing how the selective pressure  
 410 created by the vaccine is stronger when the cell  
 411 relies heavily on the production of the public  
 412 good for its fitness (Figure 7). We can also ob-  
 413 serve that the vaccine efficacy threshold is lower  
 414 when the proportion of the public good that is  
 415 shared is high, illustrating how competition be-  
 416 tween producers and cheaters for access to the  
 417 public good acts synergically with the vaccine  
 418 against producers (Figure 7, columns). Similarly,

419 it decreases when the private good production  
 420 increases, illustrating the selective advantage of  
 421 producing a private good rather than a public one  
 422 when the public good is targeted by an highly  
 423 efficient vaccine (Figure 7, rows).

424 The scenarios presented above, while mention-  
 425 ing mutations and changes in frequency, are  
 426 really static in nature. They do not take into  
 427 account the adaptive dynamics of the population.  
 428 Let's now consider a homogeneous population,  
 429 much like what was proposed in the first scenar-  
 430 io. The fitness of any cell in this scenario is  
 431 given in Equation 5 but let's name the fitness  
 432  $W_{3,1}$  and the public good production  $q_{3,1}$  for the  
 433 sake of clarity. Let's now consider a mutant cell,  
 434 with a production of the public good  $q_{3,2}$ . If we  
 435 consider a very large population such that  $x_{3,1} =$   
 436 1 (where  $x_{3,1}$  is the proportion of cells with the  
 437 wild phenotype) when the mutant cell emerges

$$\eta'_{2,1} = 1 - \frac{\left( (1-g)^{\frac{1}{\alpha}} - (1-q_{2,1}-g)^{\frac{1}{\alpha}} \right) g}{(1-\lambda)(1-q_{2,1}-g)^{\frac{1}{\alpha}} q_{2,1}} \quad (17)$$

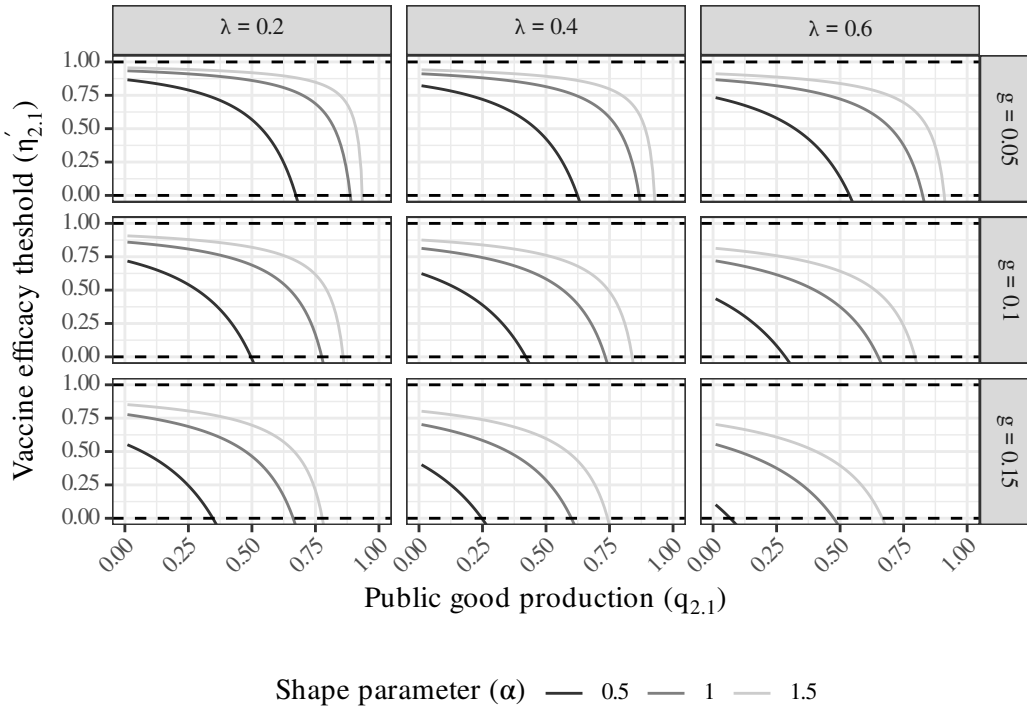

Figure 7: Vaccine efficacy threshold ( $\eta'_{2,1}$ ) as a function of the public good production ( $q_{2,1}$ ) for different values of the shape parameter ( $\alpha$ ), fraction of the good that is shared ( $\lambda$ ) and private good production ( $g$ ). The dashed lines indicate the natural boundaries of  $\eta'_{2,1}$ .

438 in the population, the fitness of the mutant cell is  
 439 given in Equation 18.

440 The mutant cell can multiply if its fitness is  
 441 higher than the fitness of resident cells, i.e., if  
 442  $W_{3.2} > W_{3.1}$  or, in other words, if its invasion  
 443 fitness is positive, i.e., if  $\omega_{3.2} > 0$  with  $\omega_{3.2} =$   
 444  $W_{3.2} - W_{3.1}$ . We can observe that there are  
 445 varieties of situations where the mutant strain  
 446 can invade and replace the resident strain popu-  
 447 lation (Figure 8, dark grey areas) and varieties  
 448 of situations where it can not (Figure 8, light  
 449 grey areas). In the first situation, the proportion  
 450 of mutant cells,  $x_{3.2}$ , increases and eventually  
 451 reaches one, while the proportion of resident  
 452 cells,  $x_{3.1}$ , decreases and eventually reaches zero.  
 453 In the second situation,  $x_{3.2}$  stays zero and  $x_{3.1}$   
 454 stays one.

455 Interestingly, if we reciprocally calculate the  
 456 invasion fitness of resident strains,  $\omega_{3.1}$ , we dis-  
 457 cover that there are also  $q_{3.1}$  and  $q_{3.2}$  values  
 458 combinations where both phenotypes can invade  
 459 each other, leading to coexistence (Figure 8,  
 460 medium gray areas). This implies that  $x_{3.1}$  will

461 decrease but not reach zero while  $x_{3.2}$  will  
 462 increase but not reach one, contrarily to the sit-  
 463 uations shown in the dark grey areas. In other  
 464 words, in light grey areas, we have  $\omega_{3.1} > 0$  and  
 465  $\omega_{3.2} \leq 0$ ; in dark grey areas, we have  $\omega_{3.1} \leq 0$   
 466 and  $\omega_{3.2} > 0$ , and in medium gray areas we have  
 467  $\omega_{3.1} > 0$  and  $\omega_{3.2} > 0$ .

468 Using an extension of Equation 16 for which  
 469 “cheater” cells have a public good production  
 470  $q_{2.2} > 0$ , we observe that the dark, light and  
 471 medium grey area on Figure 8 correspond  
 472 to  $x_{2.1}^* < 0$ ,  $x_{2.1}^* > 1$  and  $0 < x_{2.1}^* < 1$ , respec-  
 473 tively (not shown).

474 We can show that there exists a singular public  
 475 good production value,  $q_{3.1}^*$ , that should ulti-  
 476 mately be reached when a long enough time  
 477 has been spent and mutations occur altering the  
 478 public good production. A phenotype producing  
 479 such an amount of public good cannot be invaded  
 480 and is thus an evolutionary stable strategy (ESS).  
 481 This value is

---

$$W_{3.2} = (1 - q_{3.2} - g)((1 - \lambda)(1 - \eta)q_{3.2} + \lambda(1 - \eta)q_{3.1} + g)^\alpha \quad (18)$$

---

Figure 8: Pairwise invasibility plot. Dark grey areas indicate a positive invasion fitness while light grey areas indicate a negative invasion fitness. Medium gray areas indicate mutual invasion and thus coexistence. White areas indicate undefined space ( $q_{(\cdot)} > 1 - g$ ). Other parameters values are  $\alpha = 0.5$ ,  $\eta = 0.2$ ,  $\lambda = 0.1$  and  $g = 0.05$ .

$$q_{3.1}^* = \frac{\alpha}{\alpha + \frac{1}{1-\lambda}} - g \frac{\alpha(1-\eta) + \frac{1}{1-\lambda}}{(1-\eta)(\alpha + \frac{1}{1-\lambda})}. \quad (19)$$

482 Interestingly, we see that the higher the shared  
 483 portion of the public good ( $\lambda$ ), the lowest the  
 484 value of  $q_{3.1}^*$ . Reciprocally, the lower the value  
 485 of  $\lambda$ , the highest the value of  $q_{3.1}^*$  and, for  $\lambda =$   
 486  $0$  we have  $q_{3.1}^* = q_1^*$ , i.e., the ESS matches the  
 487 optimal strategy. This means that, for  $\lambda \neq 0$ , the  
 488 ESS is less than optimal (Figure 9B). In the end, a  
 489 clonal population should appear with a lower fit-  
 490 ness than the maximal one it could theoretically  
 491 achieve (Figure 9C).

492 Note that, on Figure 9, new mutants appear even  
 493 when the population is not clonal (Figure 9A),  
 494 i.e., the fitness of mutants is not equal to the one

495 formulated by Equation 18 but to the one given  
 496 by Equation 1. Moreover, the “final” public good  
 497 production and clonal fitness are different than  
 498 the theoretical values because of the small popu-  
 499 lation size and high mutation rate, leading to drift  
 500 (see Supplementary material).

Let  $\eta'_{3.1}$  be the vaccine efficacy threshold above  
 501 which the evolutionary stable public good pro-  
 502 duction is equal to zero, i.e., the value such that  
 503  $q_{3.1}^*(\eta = \eta'_{3.1}) = 0$ . This value is  
 504

$$\eta'_{3.1} = 1 - \frac{g}{\alpha(1-\lambda)(1-g)}, \quad (20)$$

and we can show that for all  $\eta > \eta'_{3.1}$ ,  $q_{3.1}^* < 0$ .  
 505 This formula is similar to Equation 7 with the  
 506 only difference being the addition of the propor-  
 507

Figure 9: Evolution of the public good production when mutations occur. **(A)** Proportion of cells of different phenotypes ( $x_i$ ,  $i$  as colors) as a function of time. Only phenotypes becoming dominant are shown to increase readability. **(B)** Public good production of the dominant phenotype ( $q_i$ ) as a function of time. The dotted line represents the optimal public good production according to Equation 6 and the dashed line represents the evolutionary stable public good production according to Equation 19. **(C)** Fitness of the dominant phenotype ( $W_i$ ) if it was in a clonal population. The dotted line represents the fitness with the optimal public good production and the dashed line represents the fitness with the evolutionary stable public good production (Equation 1). Other parameters values are  $\alpha = 0.5$ ,  $\eta = 0.2$ ,  $\lambda = 0.4$  and  $g = 0.05$ . For details on the simulator, see the Supplementary material.

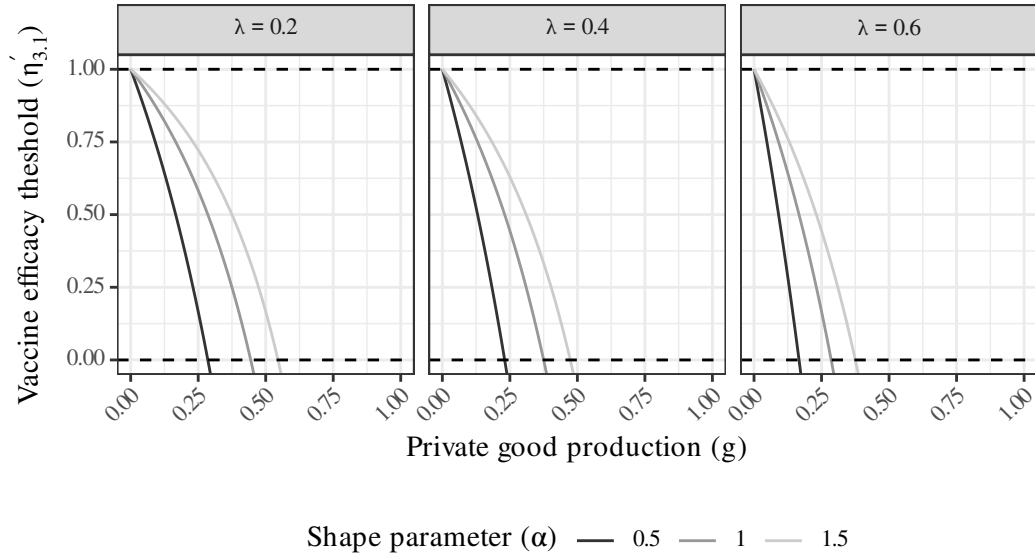

Figure 10: Vaccine efficacy threshold ( $\eta'_{3,1}$ ) as a function of the private good production ( $g$ ) for different values of the shape parameter ( $\alpha$ ) and fraction of the good that is shared ( $\lambda$ ). The dashed lines indicate the natural boundaries of  $\eta'_{3,1}$ .

508 tion of the public good that is shared with other  
 509 cells ( $\lambda$ ) in the formula. We observe that the  
 510 higher this value, the lower the vaccine efficacy  
 511 threshold (Figure 10). Also, and similarly to what  
 512 was shown earlier, we observe that the highest  
 513 the production of the private good, the lowest  
 514 the vaccine threshold. As before, we can show  
 515 that there is a private good production thresh-  
 516 old above which the public good production is  
 517 counter-selected whatever the vaccine efficacy.

518 This value is

$$g'_{3,1} = \frac{(1-\lambda)\alpha}{(1-\lambda)\alpha + 1}. \quad (21)$$

519 It implies that the higher the value of  $\lambda$ , i.e., the  
 520 more the public good is shared among other cells,  
 521 the lower the private good production needed  
 522 for the public good production to be counter-  
 523 selected.

## 524 Discussion

525 The first model we presented, which we may call  
 526 the “one-strain” scenario and that we formulated  
 527 with Equation 5, may be plausible on a short  
 528 time scale. At the beginning of an infection, an  
 529 individual may be infected only by one variant  
 530 from a bacterial population because of the bottle-  
 531 neck applied when a pathogen jumps from one

host to the next (De Ste Croix et al., 2020; Zwart  
 & Elena, 2015) or because the previous host was  
 already carrying a clonal population of bacteria,  
 for example because of the use of an antibiotics  
 therapy (McVicker et al., 2014). We showed with  
 this model that the use of a vaccine targeting the  
 public good should decrease the fitness of the  
 cells, a finding that is of particular interest from  
 a medical point of view. First, because a decrease  
 in the fitness should lead to a decrease in the  
 multiplication rate and thus a decrease in the  
 bacterial load, which is correlated to morbidity  
 and mortality in many pathogenic systems such  
 as *Neisseria meningitidis* (Darton et al., 2009),  
*Streptococcus pneumoniae* (Rello et al., 2009) or  
*Mycobacterium tuberculosis* (Pasipanodya et al.,  
 2015) infections. Second, because the decrease in  
 fitness can be so high that the production of the  
 public good may be counter-selected. This is par-  
 ticularly interesting if the public good targeted by  
 the vaccine is a virulent factor, like the diphthe-  
 ria toxin is targeted by modern vaccines against  
*Corynebacterium diphtheriae* (Pappenheimer Jr.,  
 1984).

We also showed with this model that vaccines  
 create novel environmental conditions under  
 which the most efficient phenotype shifts. Inter-  
 estingly, this finding only holds when there

560 exists an alternative metabolic pathway making  
561 the production of the vaccine-targeted public  
562 good non-mandatory for the multiplication or  
563 survival of the cells. This illustrates how vaccines  
564 alter the selective pressures weighting on (path-  
565 ogenic) bacteria, something largely described in  
566 the literature with species such as *Streptococcus*  
567 *pneumoniae* (Brueggemann et al., 2007) and *Bor-*  
568 *detella pertussis* (Lecorvaisier, 2024; Lefrancq et  
569 al., 2022).

570 The second model, which we may call the “coop-  
571 erator-cheater” scenario and that we formulated  
572 with Equation 9 and Equation 10, may be more  
573 plausible than the first one at an intermediate  
574 time scale, when a mutation leading to the  
575 appearance of a phenotype not producing the  
576 public good had time to emerge and increase  
577 in frequency. We showed with this model that,  
578 in the absence of a vaccine, the relationship  
579 between producers and cheaters is driven by the  
580 production of the different types of goods and  
581 the accessibility of public goods. Intuitively, one  
582 could think that producing a public good in the  
583 presence of cheaters while a alternative private  
584 metabolic pathway exists should be counter-  
585 selected, and that cooperators should ultimately  
586 vanish with the capacity of producing said public  
587 good (Black Queen hypothesis). This apparent  
588 problem finds its solution if we consider that pub-  
589 lic goods are only partly public and thus can that  
590 cooperators cells better exploit there own public  
591 good production than other cells, improving the  
592 global fitness of cells producing both private and  
593 (partially) public goods (Bruce et al., 2017; Lerch  
594 et al., 2022).

595 When a vaccine is used, the environmental  
596 conditions shift and the advantage given to pro-  
597 ducers diminishes, increasing the frequency of  
598 the cheater phenotype. Nevertheless, for produc-  
599 ers to completely vanish, and similarly to what  
600 was concluded with the one-strain model, it is  
601 necessary that an alternative metabolic exists to  
602 compensate for the loss of the public good pro-  
603 duction function in the population.

604 The first and second models have similar conclu-  
605 sions in showing that increasing the vaccine  
606 efficacy leads to a decrease in the fitness of cells  
607 producing the public good. But the cooperato-  
608 r-cheater model gives us a new insight, as we  
609 saw that the decrease in the fitness and thus  
610 frequency of producers was amplified by the  
611 presence of the competitive, cheater phenotype.  
612 In the case where the public good is a viru-  
613 lence factor, this finding implies that designing  
614 vaccines specifically targeting such virulence-re-  
615 lated public goods could act synergically with the  
616 competition by cheater cells to lead to the erad-  
617 ication of pathogenic cells, something already  
618 found in a between-hosts model of transmission  
619 of diphtheria (Lecorvaisier et al., 2024).

620 The third model, which we may call the “inva-  
621 sion” scenario and that we formulated with  
622 Equation 18, can be plausible at a long time scale,  
623 when multiple mutations have time to appear.  
624 This model is again interesting when compared  
625 to the precedent ones. The one-strain model gave  
626 us the optimal (in term of fitness) public good  
627 production. This model shows that, in the long  
628 run, natural selection, through competition to the  
629 access of public goods, favors a less-than-optimal  
630 public good production. As the cooperator-coop-  
631 erator model illustrated, this model shows that  
632 coexistence between high- and low-producing  
633 cells is possible, but the population should ulti-  
634 mately converge toward a clonal phenotype.

635 When looking at the effect of a vaccine, we dis-  
636 covered that the higher the vaccine efficacy, the  
637 lowest the ESS of public good production. For  
638 really high values of the vaccine efficacy, it is  
639 even possible that the ESS is to stop producing  
640 the public good. In this case, vaccination appears  
641 as a viable strategy to drive the evolution of  
642 pathogens toward non-production of a public  
643 good. As discussed earlier, this is particularly  
644 interesting in the case where the public good is a  
645 virulence factor.

646 Our work shows that cheating may emerge as a  
647 medium-term strategy without being evolution-  
648 ary stable. From a theoretical ecology point of  
649 view, this means that cheaters should eventually  
650 disappear from the population. Nevertheless, in  
651 real-life settings, environmental conditions are  
652 so stochastic and perturbations occurs at such  
653 high rates that it is unlikely that a population

654 eventually reaches the theoretical ESS. Moreover,  
 655 in this model, the ESS relies on parameter values  
 656 that may change over time, such as the vaccine  
 657 efficacy, which may change one way by the se-  
 658 lection of novel bacterial alleles diminishing the  
 659 efficacy, and the other way by the deployment of  
 660 new vaccines with a higher efficacy. This implies  
 661 that the evolution of pathogens following the use  
 662 of vaccines should be carefully monitored and  
 663 studied to evaluate the effects of this selective  
 664 pressure.

665 As any modelling work, our study has some flaws  
 666 and limits. One of these is that the public good  
 667 production is considered as constant, while in  
 668 real biological settings the production may fluc-  
 669 tuate with time and the resource availability. For  
 670 example, the diphtheria toxin production in *C.*  
 671 *diphtheriae* is conditioned by the iron availability  
 672 in the host (Parveen et al., 2019).

673 Another important limit is that our analysis  
 674 focuses on the within-host competitive dynam-  
 675 ics between strains, without considering the  
 676 between-hosts dynamics and the competition for  
 677 new hosts. It would be interesting to study how  
 678 selective pressure at the within-host scale could  
 679 alter the between-hosts spread of novel strains in  
 680 a vaccination context. For example, we hypoth-  
 681 esize that the population heterogeneity in the  
 682 vaccine status can strongly alter the competitive  
 683 dynamics between multiple strains.

684 Despite these limits, our model has strong impli-  
 685 cations for vaccine development and vaccination  
 686 strategies. We show that vaccine strategies have  
 687 complex evolutive outcomes that must be studied  
 688 before being deployed, and that ecological rela-  
 689 tionships between organisms can be used in the  
 690 fight against pathogenic strains or species.

866 **Supplementary material**867 **Stochastic model for the cooperator-cheater model**

868 We used the model described in Equation 9 and Equation 10 to simulate the propagation of the two  
 869 phenotypes, cooperator (2.1) and cheater (2.2). In these simulations, the parameters were chosen as  
 870  $\alpha = 0.5$ ,  $\eta = 0.4$ ,  $g = 0.05$  and  $\lambda = 0.2$ . Three different values of  $q_{2,1}$  were tested: 0.35, 0.5 and 0.75.  
 871 Five initial values of  $x_{2,1}$  were arbitrarily chosen and for each of these initial  $x_{2,1}$  values a simulation  
 872 was run with each of the three  $q_{2,1}$  values. Each simulation went on for 100 time steps, one time step  
 873 being equal to one generation. The population was fixed at 10,000 cells. Each time step consisted in  
 874 two steps:

- 875 • Calculating the fitness value ( $W_i$ ) of all of the cells using Equation 9 and Equation 10.
- 876 • Picking up the phenotype of the new 10,000 cells using a multinomial random trial where the
- 877 probabilities are proportional to the values of  $W_i$ .

878 Then, the model continued until the final time step was reached.

879 **Stochastic model for the adaptive dynamics model**

880 We used the model described in Equation 1 to simulate the propagation of mutant strain(s) with  
 881 different public good production phenotypes. In these simulations, the parameters were chosen as  $\alpha =$   
 882  $0.5$ ,  $\eta = 0.2$ ,  $g = 0.05$  and  $\lambda = 0.4$ . An initial value  $q = 0.75$  was used for the whole population. The  
 883 simulation went on for 5,000 time steps, one time step being equal to one generation. The population  
 884 was fixed at 1,000 cells. Each time step consisted in three steps:

- 885 • Establishing the list of new individuals presenting a mutation.
- 886 • Calculating the fitness value ( $W_i$ ) of all of the cells using Equation 1.
- 887 • Picking up the phenotype of the new 1,000 cells using a multinomial random trial where the proba-
- 888 bilities are proportional to the values of  $W_i$ .

889 Then, the model continued until the final time step was reached.

890 Mutations were modelled as follows: at each time step, each new cell has a certain probability of  
 891 developing a mutation altering its public good production, fixed at  $P_{\text{mut}} = 10^{-3}$  (so, a mutation rate  
 892  $\mu = 10^{-3}$  per generation), meaning that on average one new mutation would appear per generation.  
 893 For each cell presenting a mutation, its phenotype was calculated by incrementing its parent phenotype  
 894 by a value picked from a uniform distribution between  $-0.1$  and  $+0.1$  (with respect to  $q \in [0, 1 - g]$ ).

895 **Proofs**

896 *Equation 6*

897 We can write  $W_1$  as a function of  $q_1$ :

$$W_1(q_1) = (1 - q_1 - g)((1 - \eta)q_1 + g)^\alpha. \quad (22)$$

898 In order to find the  $q_1$  value to maximize  $W_1$ , we derivate  $W_1$ , giving:

$$W_1'(q_1) = ((1 - \eta)q_1 + g)^{\alpha-1}(-(\alpha + 1)(1 - \eta)q_1 - g + \alpha(1 - \eta)(1 - g)). \quad (23)$$

899 In this form, the first term is positive, so the sign of  $W_1'$  is determined by the second, which is a linear  
 900 function of  $q_1$  with a slope  $-(\alpha + 1)(1 - \eta) < 0$ . Moreover, this term vanishes for

$$q_1^* = \frac{\alpha}{\alpha + 1} - g \frac{\alpha(1 - \eta) + 1}{(1 - \eta)(\alpha + 1)}. \quad (24)$$

901 Hence, the derivative is positive on  $[0, q_1^*]$  and negative on  $[q_1^*, 1]$ . Therefore, the function  $W_1$  reaches  
 902 its maximum value on  $[0, 1]$  for  $q_1 = q_1^*$ .

903 *Equation 7*

904 We know that

$$\begin{aligned} q_1^* &= \frac{\alpha}{\alpha + 1} - g \frac{\alpha(1 - \eta) + 1}{(1 - \eta)(\alpha + 1)} \\ q_1^* &= \frac{\alpha(1 - \eta) - g\alpha(1 - \eta) - g}{(1 - \eta)(\alpha + 1)} \\ q_1^* &= \frac{\alpha(g - 1)\eta + \alpha(1 - g) - g}{(1 - \eta)(\alpha + 1)}. \end{aligned} \quad (25)$$

905 The denominator is always positive because  $0 \leq \eta \leq 1$  and  $\alpha > 0$ , so  $q_1^*$  has the same sign as its  
 906 numerator. The numerator is a linear function of  $\eta$  with the slope  $\alpha(g - 1) \leq 0$  (because  $g \leq 1$ ) and  
 907 vanishes for

$$\eta'_1 = 1 - \frac{g}{\alpha(1 - g)}. \quad (26)$$

908 Therefore,  $q_1^*$  is positive when  $\eta \leq \eta'_1$  and negative when  $\eta \geq \eta'_1$ .

909 *Equation 16*

910 We search the value  $x_{2.1}$  for which  $W_{2.1} = W_{2.2}$ . We posit  $C_{2.1} = 1 - q_{2.1} - g$  and  $C_{2.2} = 1 - g$  and  
 911 we have

$$\begin{aligned} W_{2.1} &= W_{2.2} \\ \Leftrightarrow C_{2.1}((1 - \lambda)(1 - \eta)q_{2.1} + g + \lambda(1 - \eta)x_{2.1}q_{2.1})^\alpha &= C_{2.2}(g + \lambda(1 - \eta)x_{2.1}q_{2.1})^\alpha \\ \Leftrightarrow C_{2.1}^{\frac{1}{\alpha}}((1 - \lambda)(1 - \eta)q_{2.1} + g + \lambda(1 - \eta)x_{2.1}q_{2.1}) &= C_{2.2}^{\frac{1}{\alpha}}(g + \lambda(1 - \eta)x_{2.1}q_{2.1}) \\ \Leftrightarrow C_{2.1}^{\frac{1}{\alpha}}((1 - \lambda)(1 - \eta)q_{2.1} + g) + C_{2.1}^{\frac{1}{\alpha}}\lambda(1 - \eta)x_{2.1}q_{2.1} &= C_{2.2}^{\frac{1}{\alpha}}g + C_{2.2}^{\frac{1}{\alpha}}\lambda(1 - \eta)x_{2.1}q_{2.1} \\ \Leftrightarrow C_{2.1}^{\frac{1}{\alpha}}\lambda(1 - \eta)x_{2.1}q_{2.1} - C_{2.2}^{\frac{1}{\alpha}}\lambda(1 - \eta)x_{2.1}q_{2.1} &= C_{2.2}^{\frac{1}{\alpha}}g - C_{2.1}^{\frac{1}{\alpha}}((1 - \lambda)(1 - \eta)q_{2.1} + g) \\ \Leftrightarrow x_{2.1} \left( C_{2.1}^{\frac{1}{\alpha}}\lambda(1 - \eta)q_{2.1} - C_{2.2}^{\frac{1}{\alpha}}\lambda(1 - \eta)q_{2.1} \right) &= C_{2.2}^{\frac{1}{\alpha}}g - C_{2.1}^{\frac{1}{\alpha}}((1 - \lambda)(1 - \eta)q_{2.1} + g) \\ \Leftrightarrow x_{2.1} &= \frac{C_{2.2}^{\frac{1}{\alpha}}g - C_{2.1}^{\frac{1}{\alpha}}((1 - \lambda)(1 - \eta)q_{2.1} + g)}{C_{2.1}^{\frac{1}{\alpha}}\lambda(1 - \eta)q_{2.1} - C_{2.2}^{\frac{1}{\alpha}}\lambda(1 - \eta)q_{2.1}}. \end{aligned} \quad (27)$$

912 Reorganizing the last line of Equation 27 and recalling that  $C_{2.1} = 1 - q_{2.1} - g$  and  $C_{2.2} = 1 - g$ , we  
 913 eventually obtain the value of  $x_{2.1}^*$  as

$$x_{2.1}^* = \frac{(1 - q_{2.1} - g)^{\frac{1}{\alpha}}((1 - \lambda)(1 - \eta)q_{2.1} + g) - (1 - g)^{\frac{1}{\alpha}}g}{\lambda(1 - \eta) \left( (1 - g)^{\frac{1}{\alpha}} - (1 - q_{2.1} - g)^{\frac{1}{\alpha}} \right) q_{2.1}}. \quad (28)$$

914 *Equation 19*

915 We can interpret the function  $\omega_{3.2}$  as a function of two variables,

$$\begin{aligned} F(q_{3.1}, q_{3.2}) &:= (1 - q_{3.2} - g)((1 - \lambda)(1 - \eta)q_{3.2} + g + \lambda(1 - \eta)q_{3.1})^\alpha \\ &\quad - (1 - q_{3.1} - g)((1 - \eta)q_{3.1} + g)^\alpha \end{aligned} \quad (29)$$

916 where  $q_{3,1}$  represents the public good production of the resident cell and  $q_{3,2}$  the public good produc-  
 917 tion of a mutant cell. We can easily verify for all  $q_{3,1} \in [0, 1]$ ,  $F(q_{3,1}, q_{3,1}) = 0$  which is consistent with  
 918 the biological meaning of  $F$ . We call  $f_{q_{3,1}} : q_{3,2} \mapsto F(q_{3,1}, q_{3,2})$  the function that gives the invasion  
 919 fitness as a function of the mutant cell's public good production  $q_{3,2}$ , for a fixed resident cell public  
 920 good production  $q_{3,1}$ . The singular value we seek corresponds to a resident public good production  
 921 that cannot be invaded by any mutant. Mathematically, this amounts to finding a value  $q_{3,1}^*$  such that  
 922  $f_{q_{3,1}}^*(q_{3,2}) \leq 0, \forall q_{3,2} \in [0, 1]$ .

923 Let us show, using a Analysis-Synthesis reasoning, that there exists a unique  $q_{3,1}^*$  value in  $]0, 1[$ , the  
 924 boundary cases being trivial.

925 **Analysis:** Assume that there exists a value  $q_{3,1}^* \in ]0, 1[$  such that  $f_{q_{3,1}^*}(q_{3,2}) \leq 0, \forall q_{3,2} \in [0, 1]$ . Since  
 926  $f_{q_{3,1}^*}(q_{3,1}^*) = F(q_{3,1}^*, q_{3,1}^*) = 0$ , it implies that  $q_{3,1}^*$  is a minimum of the function on the open interval  
 927  $]0, 1[$ . Therefore, its derivative vanishes at this point  $f'_{q_{3,1}^*}(q_{3,1}^*) = 0$  and

$$f_{q_{3,1}^*}(q_{3,2}) = (1 - q_{3,2} - g)((1 - \lambda)(1 - \eta)q_{3,2} + \lambda(1 - \eta)q_{3,1}^* + g)^\alpha - (1 - q_{3,1}^* - g)((1 - \eta)q_{3,1}^* - g)^\alpha. \quad (30)$$

928 So we compute the derivative

$$f'_{q_{3,1}^*}(q_{3,2}) = -((1 - \lambda)(1 - \eta)q_{3,2} + \lambda(1 - \eta)q_{3,1}^* + g)^\alpha + (1 - q_{3,2} - g)\alpha(1 - \lambda)(1 - \eta)((1 - \lambda)(1 - \eta)q_{3,2} + \lambda(1 - \eta)q_{3,1}^* + g)^{\alpha-1}, \quad (31)$$

929 and then apply to  $q_{3,2} = q_{3,1}^*$ :

$$f'_{q_{3,1}^*}(q_{3,1}^*) = -((1 - \eta)q_{3,1}^* + g)^\alpha + (1 - q_{3,1}^* - g)\alpha(1 - \lambda)(1 - \eta)((1 - \eta)q_{3,1}^* + g)^{\alpha-1} = ((1 - \eta)q_{3,1}^* + g)^{\alpha-1}(- (1 - \eta)q_{3,1}^* - g + (1 - g)\alpha(1 - \lambda)(1 - \eta) - q_{3,1}^*\alpha(1 - \lambda)(1 - \eta)). \quad (32)$$

930 We know  $f'_{q_{3,1}^*}(q_{3,1}^*) = 0$ , however,  $(1 - \eta)q_{3,1}^* + g > 0$  and  $\lambda \neq 1$  so

$$\begin{aligned} & -\frac{(1 - \eta)q_{3,1}^*}{1 - \lambda} - \frac{g}{1 - \lambda} + (1 - g)\alpha(1 - \eta) - q_{3,1}^*\alpha(1 - \lambda)(1 - \eta) = 0 \\ \Leftrightarrow & q_{3,1}^* \left( \frac{(1 - \eta)}{1 - \lambda} + \alpha(1 - \eta) \right) = (1 - g)\alpha(1 - \eta) - \frac{g}{1 - \lambda} \\ \Leftrightarrow & q_{3,1}^* = \frac{(1 - g)\alpha(1 - \eta)}{\alpha(1 - \eta) + \frac{1 - \eta}{1 - \lambda}} - g \frac{1}{(1 - \eta) + \alpha(1 - \eta)(1 - \lambda)} \\ \Leftrightarrow & q_{3,1}^* = \frac{\alpha}{\alpha + \frac{1}{1 - \lambda}} - g \frac{\alpha(1 - \eta) + (1, 1 - \lambda)}{(1 - \eta)(\alpha + \frac{1}{1 - \lambda})}. \end{aligned} \quad (33)$$

931 If  $q_{3,1}^*$  exists, it must have this form and therefore is unique.

932 **Synthesis:** Let  $q_{3,1}^*$  as in the last line of Equation 33, let us verify  $f_{q_{3,1}^*}(q_{3,2}) \leq 0, \forall q_{3,2} \in [0, 1]$ . From  
 933 Equation 33 we can write the derivative of  $f$  in the form

$$f'_{q_{3,1}^*}(q_{3,2}) = ((1 - \lambda)(1 - \eta)q_{3,2} + \lambda(1 - \eta)q_{3,1}^* + g)^{\alpha-1} \times [-(1 - \lambda)(1 - \eta)(\alpha + 1)q - (1 - \eta)(\lambda q_{3,1}^* - (1 - g)(1 - \lambda)\alpha) - g]. \quad (34)$$

934 The first term is always positive, as it is a sum of positive terms; therefore, the derivative has the  
 935 same sign as the second term. The second term is linear in  $q_{3,2}$  with a slope  $-(1 - \lambda)(1 - \eta)(\alpha +$   
 936  $1) < 0$  and vanishes at  $q_{3,1}^*$  (which is easily verified). Hence, the derivative is positive on  $[0, q_{3,1}^*]$  and

937 negative on  $[q_{3.1}^*, 1]$ . Therefore, the function is increasing on  $[0, q_{3.1}^*]$  and decreasing on  $[q_{3.1}^*, 1]$ . Since  
 938  $f_{q_{3.1}^*}(q_{3.1}^*) = 0$ , the function is always negative on  $[0, 1]$ . Thus, the expression of  $q_{3.1}^*$  in the last line of  
 939 Equation 33 satisfies  $f_{q_{3.1}^*}(q_{3.2}) \leq 0, \forall q \in [0, 1]$ .

940 **Conclusion:** There exists one and only one value of production of public good  $q_{3.1}^*$  for which the  
 941 phenotype cannot be invaded, the form of  $q_{3.1}^*$  is

$$q_{3.1}^* = \frac{\alpha}{\alpha + \frac{1}{1-\lambda}} - g \frac{\alpha(1-\eta) + \frac{1}{1-\lambda}}{(1-\eta)(\alpha + \frac{1}{1-\lambda})}. \quad (35)$$

942 *Equation 20*

943 Similarly to the previous case (see proof of Equation 7),  $q_{3.1}^*$  can be expressed as a function of  $\eta$  as

$$q_{3.1}^* = \frac{\eta\alpha(g-1) + \alpha - g\alpha - \frac{g}{1-\lambda}}{(1-\eta)(\alpha + \frac{1}{1-\lambda})}. \quad (36)$$

944 In this form, the denominator is positive, so the sign of  $q_{3.1}^*$  is determined by the numerator, which is  
 945 a linear function of  $\eta$  with a slope  $\alpha(g-1) < 0$ . Moreover, the numerator vanishes for

$$\eta'_{3.1} = 1 - \frac{g}{\alpha(1-\lambda)(1-g)}. \quad (37)$$

946 Therefore,  $q_{3.1}^*$  is positive when  $\eta \leq \eta'_{3.1}$  and negative when  $\eta \geq \eta'_{3.1}$ .
