**17 Abstract**

18           Predicting the level of damage caused by deer browsing in young plantations is important  
19 for selecting appropriate damage control measures. In this study, we examined a method for  
20 assessing the level of deer damage in young Sugi (*Cryptomeria japonica*) plantations by observing  
21 field signs of deer. First, a questionnaire survey was conducted to obtain information about the  
22 damage caused by deer browsing on planted trees and the extent of field signs, such as browsing  
23 marks and deer fecal pellets in young plantations where deer-proof fences were installed. The extent  
24 of field signs was recorded as qualitative data (i.e., "None", "A few", and "Many"). A multiple  
25 correspondence analysis (MCA) of these relationships revealed a relationship between the extent of  
26 deer damage in young plantations and the presence of five field signs (browsing marks, bark  
27 stripping marks, fecal pellets, trails and tracks). Based on the coordinate values of each field sign  
28 obtained using the MCA, the extent of each field sign was scored, and the total value was calculated  
29 as the deer impact score (DISco). When the relationship between the DISco and the extent of deer  
30 damage to planted trees was subjected to a logistic regression analysis (LRA), the DISco was found  
31 to be a significant explanatory variable and the LRA was an effective model (AUC of 0.7122 and  
32 0.7794, respectively) for predicting the probability of stand damage and High stand damage.  
33 Therefore, the DISco was shown to be an effective tool for assessing the impact of deer in young  
34 Sugi plantations.

37

## 38 **Introduction**

39           Damage to natural vegetation and plantations caused by browsing deer has been widely  
40 reported (Gill 1992; Côté et al. 2004; Takatsuki 2009). In plantations, significant economic losses  
41 have been incurred due to deer browsing planted trees (Putman and Moore 1998; Côté et al. 2004).  
42 Damage caused by deer can be divided into two general types: browsing of branches and leaves  
43 shortly after planting, and bark stripping when the trees are mature (Iimura 1984; Gill 1992). The  
44 impact of deer browsing on planted trees is particularly large for several years after planting when  
45 the trees are relatively small (Iimura 1984).

46           As a result, a variety of damage control measures, including the installation of deer-proof  
47 fences, tree shelters and spray repellents, have been developed. Of these, fences and tree shelters  
48 have been used extensively in many young plantations to protect planted trees from deer damage  
49 (Masaki et al. 2017). However, it is difficult to completely protect planted trees from browsing deer  
50 using these protective tools alone. Even in young plantations where fences have been installed, there  
51 have been many reports of cases where deer have been able to cross the fence due to the fence being  
52 compromised in some way, e.g., entering through holes or over parts of the fence that have  
53 collapsed, and the deer have then caused extensive browsing damage inside the fence (Takayanagi  
54 and Yoshimura 1988; Takatsuki 2009; Oshima et al. 2014; Sakai 2018). Damage due to deer  
55 browsing has also been reported in some young plantations where tree shelters have been installed  
56 (Nomiya et al. *submitted to same JFR special issue*). It is presumed that the extent of damage due to  
57 deer browsing in the young plantations where fences and tree shelters have been installed is

58 proportional to the deer impact level and/or population density, but this information is lacking. The  
59 protective effect, or contribution, of each damage control measure differs depending on the impact  
60 and/or population density of the deer. In addition, the installation of fences and tree shelters has a  
61 negative effect on income generation because of the high costs for materials and installation  
62 (VerCauteren et al. 2006; Takatsuki 2009). Consequently, if damage control measures can be  
63 implemented in proportion to the level of the impact or population density of deer, then optimum  
64 damage control measures could be selected, and the cost may be minimized. Thus, an index that can  
65 be used to assess the impact level of deer after planting is needed.

66 In Japan, the population density index (Ministry of the Environment 2015; Suzuki et al.  
67 2021) estimated by the fecal pellet count method / fecal pellet group count method and the block  
68 count method (Maruyama and Furubayashi 1983; Iwamoto et al. 2000; Goda et al. 2008; Mizuki et  
69 al. 2020) are often used as indices for predicting the damage intensity caused by deer. However,  
70 these methods are time-intensive, even for one-point measurements. In addition, the resolution of  
71 the density map is approximately 5 km, which is effective for use as a wide-area index, such as the  
72 regional scale of deer population density (Suzuki et al. 2021); however, it is not possible to  
73 accurately predict the population density of a target plantation using this method. In addition, the  
74 relationship between the deer population density and the degree of forest damage by deer is not  
75 always correlated and can be influenced by a variety of factors (Ikeda 2005; Putman et al. 2011a,  
76 2011b). It is therefore necessary to consider whether other indicators can be used as a proxy for  
77 assessing damage intensity by deer in the field.

78           Indices of damage intensity by deer include assessments of browsing intensity using the  
79 height and the proportion of flowering individuals of indicator plants (Williams et al. 2000; Fletcher  
80 et al. 2001; Pavlovic et al. 2014; Blossey et al. 2017 Curtis et al. 2021), the degree of decline of  
81 understory vegetation, and the change in stand structure in the forests (Fujiki et al. 2010; Planning  
82 Committee, The Society of Vegetation Science 2011; Ohashi et al. 2014). However, evaluations  
83 based on indicator species require the ability to identify species, which can be difficult for  
84 non-experts. In addition, in surveys of large areas and/or different climatic zones, the same plants do  
85 not always grow on the forest floor, so it is difficult to survey by indicator species. Surveys focusing  
86 on browsing marks and structural changes of the understory vegetation assume that the understory  
87 vegetation is well developed when deer are absent. Therefore, it is difficult to evaluate the degree of  
88 deer disturbance in forest stands that have poorly developed understory vegetation, such as in the  
89 dark forest floors of broadleaved evergreen forests and plantations (Kiyono 1990; Ito 1996; Ito et al.  
90 2008; Yamagawa et al 2009).

91           However, a method for evaluating the impact of deer has been developed using deer signs,  
92 such as fecal pellets and evidence of bark stripping (Akashi et al. 2013). This method simply records  
93 the extent of field signs attributable to deer, and can be implemented easily by forestry managers in  
94 a short space of time. However, it is expected that the type and impact of field signs will differ  
95 depending on the climatic zone, vegetation and amount of snowfall. In addition, few studies have  
96 clarified the relationship between the impact of deer and forestry damage caused by deer.

97 Consequently, in order to predict forestry damage by deer, it is necessary to investigate the type and  
98 extent of field signs in relation to the degree of forestry damage.

99 The purpose of this study was to develop a method for assessing the level of forestry  
100 damage attributable to deer in a young Sugi (*Cryptomeria japonica*) plantation using a simple  
101 survey of field signs. Since the most common deer damage control measures in Japan include the  
102 installation of deer-proof fences, the extent and intensity of damage to planted trees inside the fences  
103 was used as an index of forestry damage levels. Thus, the following three analyses were carried out  
104 in young Sugi plantations (1- to 3-years old) in this study: 1) In order to clarify the protective effect  
105 of fences, we examined the effect of installing fences and the incidence of compromised fences on  
106 browsing damage by sika deer in young plantations; 2) The relationship between the extent of  
107 damage by deer in the plantation and the extent of field signs (e.g., browsing marks and deer fecal  
108 pellets) around the young plantation was clarified; 3) Field signs were scored and the Deer Impact  
109 Score (DISco), i.e., an index of the extent of forest damage after planting, was determined.

110

## 111 **Methods**

### 112 **1. Study area**

113 This study targeted the Kyushu and Shikoku regions of southwestern Japan (Fig. 1). Most  
114 parts of these areas belong to warm temperate and cool temperate zones, with natural vegetation that  
115 consists mostly of evergreen broadleaf forests and deciduous broadleaf forests, respectively.  
116 However, 50–60% of the forests in these areas are coniferous plantations such as Sugi (*Cryptomeria*

117 *japonica*) and Hinoki (*Chamaecyparis obtusa*) (Masaki et al. 2017). In addition, many plantations  
118 have reached the age at which the stands can be harvested, and the area of clear-cutting and  
119 re-planting is increasing. Sika deer (*Cervus nippon*) are widely distributed in many areas of these  
120 forests. In some areas, deer densities have been estimated to be 50 deer·km<sup>-2</sup> or more (Ministry of  
121 the Environment 2015). Sika deer have caused extensive damage to natural and cultivated  
122 vegetation over wide areas of the Kyushu and Shikoku regions (Ohashi et al. 2014; Suzuki et al.  
123 2021).

124

## 125 **2. Data collection**

### 126 **1) Distribution of questionnaires**

127         The extent of damage to planted trees caused by browsing sika deer and the extent of field  
128 signs of sika deer in the surrounding afforested areas were investigated using a questionnaire survey.  
129 In May 2018, we sent questionnaires to the Kyushu Regional Forest Office, the Shikoku Regional  
130 Forest Office, and the Kyushu Branch Office of Forest Management Center. The questionnaires  
131 were completed by forest officers and workers. By December 2018, 320 completed questionnaires  
132 had been collected. Of the collected questionnaires, 237 questionnaires could be used for the  
133 analysis.

134

### 135 **2) Damage to deer-proof fencing and planted trees**

136 In the Kyushu and Shikoku areas of Japan, it is common to install deer-proof fences made  
137 of nylon mesh (approximately 1.8 m high with a mesh size of 5 to 15 cm) in planted areas that are  
138 frequented by deer. In cases where the deer-proof fence was compromised by holes and/or collapsed,  
139 the browsing damage to planted trees can be extensive (Takayanagi and Yoshimura 1988; Oshima et  
140 al. 2014; Sakai 2018). Therefore, in the questionnaire survey, we also examined whether a fence had  
141 been installed and whether or not the fence had been compromised.

142 In Japan, browsing damage to planted trees by sika deer most typically occurs at heights of  
143 up to about 150 cm in plantations (Ikeda 1998; Sasaki et al. 2013; Nomiya et al. 2019). Therefore, in  
144 this study, we conducted a questionnaire survey on young Sugi plantations that were 3-years old or  
145 younger in order to target forest stands with a planted tree height of approximately 150 cm or less.

146 The browsing intensity of planted Sugi trees caused by sika deer was divided into five  
147 categories, focusing on the degree of browsing marks and tree crown shape, with reference to  
148 deCalesta et al. (2016) (Fig. 2). Planted trees with no browsing marks were classified as "Not  
149 browsed". Planted trees with the same tree crown shape as "Not browsed" and with browsing marks  
150 observed through careful observation were classified as "Lightly browsed". Planted trees with the  
151 same tree crown shape as "Not browsed" and with extensive evidence of browsing marks were  
152 classified as "Moderately browsed". Planted trees with unusual tree crown shapes that appeared like  
153 topiaries due to repeated browsing were classified as "Heavily browsed". Planted trees with only the  
154 main stem remaining due extensive browsing of leaves and branches were classified as "Severely  
155 browsed".

156 Furthermore, the distribution of the browsing intensity for each planted tree in the  
157 plantation was recorded as one of four types: None, A few, Many and All over. "None" indicates  
158 that planted trees in each browsing-intensity category did not occur in the planted area. "A few"  
159 indicates that planted trees in each browsing-intensity category can be found with careful  
160 observation. "Many" indicates that planted trees in each browsing-intensity category can be found  
161 easily in the planted area. "All over" indicates that planted trees in each browsing-intensity  
162 category are distributed throughout the planted area.

163

### 164 3) Field signs of sika deer

165 Field signs of sika deer were investigated in mature Sugi (*Cryptomeria japonica*) and  
166 Hinoki (*Chamaecyparis obtusa*) plantations and forest roads adjacent to the young plantations where  
167 the browsing intensity of the planted trees was investigated. As field signs of sika deer in the  
168 questionnaire, we recorded bark stripping of mature Sugi and Hinoki individuals in plantations (bark  
169 stripping), browsing marks on understory woody species in mature plantations, browsing marks on  
170 understory herbaceous species in mature plantations, browsing marks on roadside vegetation,  
171 dominance of unpalatable plants, deer fecal pellets, deer carcasses and/or bones, deer antlers, deer  
172 tracks, deer trails and sightings (see Table 2). The degree of bark stripping, browsing marks and the  
173 dominance of unpalatable plants were recorded in three categories ("None": no signs can be found,  
174 "A few": signs can be found with careful observation, and "Many": signs can be easily found).  
175 Regarding the dominance of unpalatable plants, the skill in identifying plant species is considered to

176 affect the responses in the questionnaire, so "unknown" was added to the response items. The extent  
177 of deer fecal pellets, carcasses and/or bones, antlers, tracks, trails and sightings were recorded in two  
178 categories: "presence" or "absence".

179

### 180 **3. Data analysis**

#### 181 **1) Level of stand damage**

182           Based on the distribution of the deer browsing intensity for each planted tree in the young  
183 Sugi plantation (Fig. 2), the level of stand damage caused by the deer was classified into four stages  
184 (Table 1). If all the planted trees were not browsed, then the level of stand damage was classified as  
185 "No damage (SDLv.0)". When the browsing intensity of the planted tree in plantation was only  
186 "lightly browsed", the stand damage level was classified as a "Low damage (SDLv.1)". If the  
187 browsing intensities of the planted trees "Heavily browsed" and "Severely browsed" are distributed  
188 in the "Many" and "All over" categories in the plantation, the stand damage level was classified as "  
189 High damage (SDLv.3)". The stand damage level between SDLv.1 and SDLv.3 was set to "Medium  
190 damage (SDLv.2)".

191

#### 192 **2) Relationship between stand damage level and deer fence status**

193           In order to clarify the impact of the presence of a fence, or areas where the fence was  
194 compromised, on the level of stand damage in a young plantation, the magnitude and proportion of

195 stand damage was calculated for each area where fences were installed and where they were  
196 compromised.

197

### 198 **3) Calculation of deer impact score (DISco)**

199 A multiple correspondence analysis (MCA) was performed to clarify the relationship  
200 between the level of stand damage and the field signs of sika deer. In the analysis, in order to  
201 eliminate the protective effect of the deer-proof fence, we only analyzed data for young plantations  
202 without deer-proof fences or plantations which had fences that were compromised (see Table 3). For  
203 the MCA, we used the responses for deer fecal pellets, browsing marks on roadside vegetation, bark  
204 stripping marks, deer trails and tracks as analysis items in the questionnaire survey (see the  
205 discussion section for details). In addition, we considered an easier method to investigate field signs  
206 of sika deer in the field. Thus, we classified the extent of three signs (deer fecal pellets, browsing  
207 marks of roadside vegetation, and bark stripping marks) into two categories, "presence" and  
208 "absence," and performed a similar MCA analysis. R 4.0.4 (R Core Team 2021) and FactoMineR  
209 package (Husson et al. 2020) were used for the analysis.

210 Based on the relative distance of the coordinate values of each field sign obtained by MCA,  
211 the degree of each field sign was assigned a score. We summed the scores for the degree of each  
212 field sign, and determined the total value of the scores as the Deer Impact Score (DISco), which is  
213 an indicator of the impact level of deer on forest stands.

214 In order to verify the validity of the DISco calculated from the field signs of sika deer, the  
215 relationship between the DISco and stand damage levels was analyzed using a generalized linear  
216 model (GLM). For the GLM analysis, we performed two types of logistic regression analysis (LRA)  
217 with different objective variables. In the two types of LRA, the explanatory variable was DISco. In  
218 the first LRA, the objective variable was the presence or absence of stand damage in the young  
219 plantation (binary data with the damaged plantation taken as 1, regardless of the stand damage level),  
220 and the probability of stand damage was estimated. In the second LRA, the objective variable was  
221 the presence or absence of the “High stand damage” in the plantation (binary data with the  
222 plantation of SDLv.3 as 1), and the probability of High stand damage was estimated. To evaluate the  
223 accuracy of the LRA, we used a receiver operating characteristic (ROC) curve (Hanley and McNeil  
224 1982). The area under the curve (AUC), which ranged between 0.5 and 1.0, was calculated based on  
225 the ROC, with greater accuracy denoted by values closer to 1.0. R 4.0.4 (R Core Team 2021), was  
226 used for the GLM.

227

## 228 **Results**

### 229 **1. Field signs associated with sika deer**

230 Table 2 shows the number of responses for each of the field signs obtained by the  
231 questionnaire survey. Questionnaires containing blank items were excluded from the analysis. The  
232 responses for the degree of bark stripping numbered 94, 96, and 24 for “None”, “A few”, and  
233 “Many”, respectively. The responses for the degree of browsing marks on understory woody species

234 numbered 130, 73, and 5 for “None”, “A few”, and “Many”, respectively. The responses for the  
235 degree of browsing marks on understory herbaceous species numbered 129, 64, and 2 for “None”,  
236 “A few”, and “Many”, respectively. The "NA" for the browsing marks on these understories  
237 indicates that the browsing marks could not be observed due to underdeveloped understory  
238 vegetation. The responses for the degree of browsing marks on roadside vegetation numbered 119,  
239 81, and 14 for “None”, “A few”, and “Many”, respectively. The responses for the degree of deer  
240 fecal pellets numbered 62, 122, and 30 for “None”, “A few”, and “Many”, respectively. The  
241 responses for the degree of dominance of unpalatable plants were 82 and 47 for “A few” and  
242 “Many”, respectively. However, the number of "unknown" responses was 85, accounting for about  
243 40% of the total in terms of the degree of dominance of unpalatable plants. Deer carcasses and/or  
244 bones, antlers, tracks, trails and sightings were confirmed at 37, 8, 126, 94 and 89 sites, respectively.

245

## 246 **2. Level of damage in each forest stand**

247 In the young plantation without deer-proof fences, SDLv 0 and 1 were observed at 19  
248 (82.6%) and 4 (17.4%) stands, respectively, and SDLv 2 and 3 were not observed in any of the  
249 stands (Table 3). Of the 214 young plantations where deer-proof fencing was installed, 56% (120  
250 stands) were found to be compromised by having holes or having collapsed (Table 3). Among the  
251 plantations where the deer-proof fencing was intact, SDLv 0 was observed at 76 stands (80.9%),  
252 SDLv 1 was observed at 14 stands (14.9%), SDLv 2 was observed at 3 stands (3.1%), and SDLv 3  
253 was observed at 1 (1.0%) (Table 3). Among the plantations where the deer-proof fencing was

254 compromised, SDLv 0 was observed at 29 stands (24.2%), SDLv 1 was observed at 24 stands  
255 (20.0%), SDLv 2 was observed at 43 stands (35.8%) and SDLv 3 was observed at 24 stands (20.0%)  
256 (Table 3).

257

### 258 3. Relationship between stand damage level and field signs of sika deer

259 Figure 3 shows the results of the MCA, which was used to analyze the relationship  
260 between stand damage level and field signs. When the degree of deer fecal pellets, bark stripping  
261 marks and browsing marks were evaluated on three levels ("None", "A few" and "Many"), the  
262 coordinate value for Dimension 1 was small for "None" for all field signs (Fig. 3 (a)). The  
263 coordinate value for Dimension 1 with SDLv.0 was smaller than that for the other stand damage  
264 levels (SDLv. 1, 2 and 3). The coordinate values for Dimension 2 were high for the "Many" degree  
265 of field signs, which is considered to be strongly influenced by deer, and small for the "A few"  
266 degree of field signs, which is considered to be weakly influenced by deer. The Dimension 2  
267 coordinate values for "Presence" of deer trails and deer tracks were between the "Many" and "A  
268 few" degrees of field signs. In addition, as the coordinate value for Dimension 2 increased, the stand  
269 damage level also increased except for SDLv. 0. In other words, Dimension 1 of the MCA was  
270 effective for distinguishing between the presence or absence of stand damage caused by deer, and  
271 Dimension 2 ranked the stand damage level.

272 When the degree of field signs was simplified (MCA analysis using all field signs as  
273 binary data "Presence" or "Absence"), the "Presence"/"Absence" of field signs and stand damage

274 levels were effectively classified by Dimension 1 of the MCA. However, there was no apparent  
275 relationship between the stand damage level and Dimension 1 and 2 of MCA (Fig. 3 (b)).

276

#### 277 **4. Calculation of the DISco**

278 Based on the results of the MCA, the "None" field sign category was assigned a value of 0  
279 (Table 4). Then, based on the relative coordinate distance for Dimension 2 in the MCA of each field  
280 sign, the degree of field signs (i.e., bark stripping marks, browsing marks and deer fecal pellets) was  
281 assigned a value of 1 for "A few" and 3 for "Many" (Table 4). The degree of field signs for  
282 "Presence" of deer trails and tracks was assigned a value of 2 (Table 4). The summed value of these  
283 field signs was up to 13, and was used as the Deer Impact Score (DISco) to evaluate the level of  
284 stand damage by sika deer.

285

#### 286 **5. Relationship between DISco and level of stand damage**

287 In the LRA, which analyzed the relationship between the presence or absence of stand  
288 damage and the DISco, the DISco was found to be a significant explanatory variable ( $p = 0.001$ ).  
289 The AUC obtained for the LRA was 0.7122, indicating that the model was effective for predicting  
290 the probability of stand damage by sika deer. The probability of stand damage increased linearly  
291 between 0 and 8 for the DISco, and was saturated when the DISco was 8 or above (Fig. 4 (a)).

292 In the LRA of the relationship between the presence or absence of High stand damage and  
293 the DISco, the DISco was found to be a significant explanatory variable ( $p < 0.001$ ). The AUC

294 obtained for the LRA was 0.7794, indicating that the model was effective for predicting the  
295 probability of High stand damage. With an increase in the DISco, the probability of High stand  
296 damage increased (Fig. 4 (b)). Thus, the probability of High stand damage by sika deer was  
297 predicted to be approximately 10% for DISco 2 and approximately 30% for DISco 8.

298

## 299 **Discussion**

### 300 **1. Relationship between stand damage by deer and broken fences**

301 Compromised fences (i.e., holes and collapsed fences) were observed in approximately  
302 60% of the young plantations (Table 2). Broken fences and damage to planted trees inside fences  
303 have been reported previously (Takatsuki 2009; Oshima et al. 2014; Sakai 2018). Deer damage  
304 (SDLv 1-3) was confirmed in 75% of the plantations where the fences were broken, and high  
305 damage (SDLv 3) was observed in 20% of the plantations (Table 2). On the other hand, in  
306 plantations where the fences were not broken, plantations with SDLv 2 and 3 were few (3% and 1%,  
307 respectively) (Table 2). Therefore, uncompromised fences have a highly protective effect. However,  
308 in cases where fences are compromised with a high probability, then it is very difficult to protect the  
309 planted trees by installing only a deer fence.

310

### 311 **2. Field signs used for DISco**

312 In this study, the DISco was calculated using five field signs: deer fecal pellets, bark  
313 stripping marks in a mature plantation, browsing marks on roadside vegetation, deer tracks and deer

314 trails. Among the questionnaire survey items, the degree of browsing damage to understory  
315 vegetation (woody and herbaceous species), the dominance of unpalatable plants, deer  
316 carcasses/bones, deer antlers and sightings were excluded from the field signs considered for  
317 calculating the DISco for the following reasons.

318         Browsing marks on the understory vegetation (woody and herbaceous plants) in mature  
319 plantations are also one of the indicators of the degree of deer damage (Fujiki et al. 2010; Kishimoto  
320 et al. 2010). However, the development of understory vegetation differs depending on the light  
321 environment in the forest floor, and there are forest stands where understory vegetation is  
322 underdeveloped regardless of deer damage (Kiyono 1990; Ito 1996; Ito et al. 2008; Yamagawa et al  
323 2009). In this study, due to the underdeveloped understory of the plantations, we could not confirm  
324 the existence of browsing marks on the understory vegetation in some plantations (Table 2).  
325 Therefore, observations of the browsing marks in the understory may underestimate the amount of  
326 browsing marks. On the other hand, the roadside environment is considered to be a good place to  
327 observe browsing marks because the vegetation grows in a relatively well-lit environment, and  
328 because it is easy to access these areas in surveys. Therefore, the degree of browsing marks was  
329 evaluated based on roadside vegetation rather than understory vegetation.

330         As deer browsing intensity increases, the number of favorite plants decreases and the  
331 number of unpalatable plants increases (Horsley et al. 2003; Suzuki et al 2008; Takatsuki 2009).  
332 Therefore, this dominance of unpalatable plants is considered to be a useful proxy for indexing the  
333 population density and/or impact of deer. In forest stands where the impact of deer is high, there is a

334 risk that browsing marks cannot be observed due to the disappearance of favorite plants. Therefore,  
335 the dominance of unpalatable plants may be an important indicator of deer impact. However, in the  
336 questionnaire survey, approximately 40% of respondents answered that the dominance of  
337 unpalatable plants was "unknown" (Table 2). This questionnaire survey targeted forest officers and  
338 workers, but it is probable that they were unable to identify unpalatable plants due to differences in  
339 their plant identification ability; consequently, the dominance of unpalatable plants was considered  
340 to be a relatively unreliable parameter for use as a proxy of deer abundance. Therefore, dominance  
341 of unpalatable plants were not used in the calculation of DISco. However, unpalatable plants that  
342 are often observed in forest stands have been clarified (Koda and Fujita 2011; Hashimoto and Fujiki  
343 2014), and should be used as an indicator of deer impact level in the future. Plant identification  
344 workshops should therefore be held before future surveys in order to provide investigators with the  
345 necessary information on unpalatable plants.

346         There were few field signs of deer carcasses/bones and antlers in the questionnaire survey  
347 (Table 2). This may be due to the narrow observation area and the limited timing of the survey in the  
348 questionnaire. The death of a deer is an accidental event, and the shedding of antlers in sika deer is  
349 limited to spring (Miura 1984). In addition, visual inspection may be affected by the season and time  
350 of the survey (Akashi et al. 2013). Therefore, these field signs were excluded from the DISco  
351 calculations.

352

### 353 **3. Validity and use of DISco**

354           The results of the MCA analysis showed that the presence or absence and amount of deer  
355 field signs (deer fecal pellets, bark stripping marks, browsing marks, deer trails and tracks)  
356 corresponded to the level of stand damage caused by sika deer (Fig. 3 (a)). Among these field signs,  
357 the level of stand damage tended to be higher in plantations where deer fecal pellets, bark stripping  
358 marks and browsing marks were recorded as "Many" (Fig. 3 (a)). On the other hand, the relationship  
359 between the level of stand damage and field signs was unclear when all of the field signs were  
360 reduced to binary data (presence or absence) for the purpose of simplifying the field sign  
361 investigation (Fig. 3 (b)). Therefore, recording the amount of deer fecal pellets, bark stripping marks  
362 and browsing marks in three categories ("None", "A few" and "Many") is important for assessing  
363 the level of stand damage by deer in young plantations.

364           The DISco (Table 4) calculated using field signs and based on the results of MCA could  
365 generally explain the probability of stand damage and high stand damage in young plantations (Fig.  
366 4). A comprehensive evaluation of multiple types of field signs (Akashi et al. 2013) can have a  
367 positive effect on the calculation of DISco. In addition, it has been reported that the probability of  
368 deer damage corresponds to the DISco, even in cases where deer damage is evaluated at tree shelter  
369 construction sites after planting (Nomiya et al. *Submitted to same JFR special issue*). Therefore, the  
370 DISco can roughly predict the probability of damage (damage risk) by deer after planting of Sugi,  
371 and this index can be used as a tool to evaluate the level of stand damage. In addition, the DISco  
372 could also be applied to evaluations of the protective effect of not only fences, but also tree shelters  
373 and repellents, and will lead to the appropriate selection of damage controls.

374           However, application of the DISco in low-density deer habitats may require caution. In  
375 terms of stand damage probability prediction (SDLv.1 or higher), damage is observed even if the  
376 DISco value is 0 (Fig. 4 (a)). Therefore, a simple survey of field signs may overlook habitats  
377 containing few deer. In particular, in forests, where the population density of deer is extremely low,  
378 it may be effective to establish line transects and carefully observe browsing marks (Otani et al.  
379 *Submitted to same JFR special issue*).

380           The method for assessing the deer impact level by the DISco described in this study has  
381 several advantages compared to other indicators of population density and deer damage level. First,  
382 the survey methods required for calculating the DISco are extremely simple. Investigators only need  
383 to check five field signs, and the time required for surveys is approximately 10 minutes (Yamagawa  
384 *unpublished data*). The surveys of field signs are conducted on forest roads (including working  
385 roads) and in mature Sugi (*Cryptomeria japonica*) and Hinoki (*Chamaecyparis obtusa*) plantations,  
386 so they can be conducted in easily accessible locations. For example, the DISco survey can be  
387 performed when a forest is visited for other reasons. Taken together, these factors mean that it is  
388 possible to conduct surveys over a wide area and in numerous locations. In addition, if the number  
389 of survey sites increases in the future, the DISco data can be mapped using location information.

390           Second, the DISco is less sensitive to the species composition and structure of understory  
391 vegetation. Surveys that cover extensive areas, especially those that span more than one climatic or  
392 vegetation zone, will often show differences in the composition of the plants growing on the forest  
393 floor (Williams et al. 2000; Fletcher et al. 2001; Pavlovic et al. 2014; Blossey et al. 2017; Curtis et

394 al. 2021), which is considered to be difficult to survey using specific indicator plants. In addition,  
395 stand structure, such as the coverage of understory vegetation and the presence or absence of  
396 browsing lines, are also important indicators of the degree of deer impact (Fujiki et al. 2010;  
397 Kishimoto et al. 2010; Ohashi et al. 2014). However, deer impact cannot be evaluated by these  
398 indicators in stands where the understory vegetation is originally underdeveloped. In this study, the  
399 level of stand damage by deer could be evaluated comprehensively using field signs that are not  
400 easily affected by the climatic and vegetation zone, such as roadside browsing marks, bark stripping  
401 marks, fecal pellets and deer trails. Therefore, this method can be applied in different regions.

402

#### 403 **Conclusion**

404 In this study, we clarified a method for assessing the level of stand damage by sika deer  
405 after planting Sugi in southwestern Japan using a simple survey of field signs in conjunction with a  
406 deer impact index used in northern Japan (Akashi et al. 2013). This simple method is less dependent  
407 on an individual investigator's abilities and can be used by many people. In order to apply the DISco  
408 more widely in the forestry field, it is necessary to improve the prediction accuracy and clarify the  
409 relationship with other indicators. Damage caused by deer is also affected by the amount of food  
410 resources (amount of favorite plants) and landscape structure around the target area (Oi and Suzuki  
411 2001; Royo et al. 2017). Future studies should also consider the abundance of favorite plants on  
412 browsing, dominance of unpalatable plants, and landscape structure as predictors of deer damage.

413

414 **Funding**

415           This study was funded by a Research Grant titled, “An improved approach to control deer  
416 damage in replanted sites in Kyushu and Shikoku” (Grant No.: 201703) from the Forestry and  
417 Forest Products Research Institute.

418

419 **Acknowledgements**

420           We would like to thank Kyushu Regional Forest Office, Shikoku Regional Forest Office  
421 and the Kyushu Branch Office of Forest Management Center for their cooperation in conducting the  
422 questionnaire survey, and Ms. N. Oneyama for their cooperation with capturing questionnaire data.

**Figure 2. Browsing intensity of planted trees**

The browsing intensity of planted Sugi trees caused by sika deer was divided into five categories, focusing on the degree of browsing marks and tree crown shape.

629

630

631

632 **Fig. 3 Multiple correspondence analysis (MCA) map with active variable categories (degree of**  
 633 **field signs) and supplementary variable categories (level of stand damage by sika deer).**

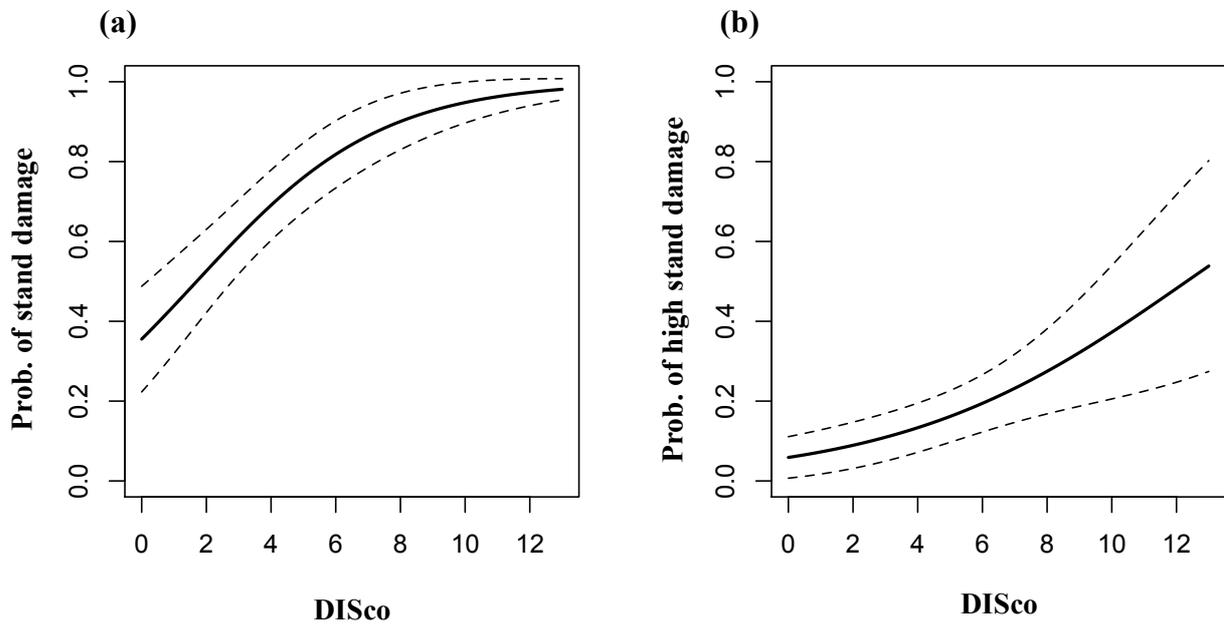

634 (a) Results of analyzing the degree of field signs (deer pellets, bark stripping marks and browsing  
 635 marks) as three-level variables (“None”, “A few” and “Many”).

636 (b) Results of analyzing the degree of all field signs as two levels (“presence” and “absence”).

637 The abbreviations in the figure indicate the type of field signs (BS: bark stripping, RB: browsing  
 638 marks on roadside vegetation, DP: deer fecal pellets, TL: deer trails, TC: deer tracks).
