## Abstract

1 Individuals' behavioral strategies are often well described by reaction norms, which are  
2 functions predicting repeatable patterns of personality, plasticity, and predictability across  
3 an environmental gradient. Reaction norms can be readily estimated using mixed-effects  
4 models and play a key role in current theories of adaptive individual variation. Unfortunately,  
5 however, it remains challenging to assess the effects of reaction norms on fitness-relevant  
6 outcomes, due to the high degree of uncertainty in random effect estimates of reaction norm  
7 parameters, also known as best linear unbiased predictors (BLUPs). Current approaches to  
8 this problem do not provide a generalized solution for modelling reaction norm effects with  
9 nonlinear structure, such as stabilizing, disruptive, balancing, and/or correlational selection,  
10 which are necessary for testing adaptive theory of individual variation. To address this  
11 issue, I present a novel solution for straightforward and unbiased estimation of linear and  
12 nonlinear reaction norm effects on fitness, applicable to both Gaussian and non-Gaussian  
13 measurements. This solution involves specifying BLUPs as random effects on behavior and  
14 fixed effects on fitness within a Bayesian multi-response model. By simultaneously accounting  
15 for uncertainty in reaction norm parameters and their causal effects on other measures,  
16 the risks accompanying classical approaches to BLUPs can be effectively avoided. I also  
17 introduce a new method for visualizing the consequences of multivariate selection on reaction  
18 norms. Simulations are then used to validate that the proposed models provide unbiased  
19 estimates across realistic parameter values, and an extensive coding tutorial is provided to  
20 aid researchers in applying this method to their own datasets in R.

## 22 1 Introduction

23 A population will evolve by natural selection whenever heritable variation occurs in fitness-relevant phenotypes  
24 (Darwin 1859). Individual differences in behavior are, therefore, a fundamental ingredient for adaptive  
25 behavioral evolution. Across taxa, repeatable individual variation is observed not only in animals' average  
26 behavior (Bell, Hankison, and Laskowski 2009), but also in the degree of behavioral responsiveness they  
27 exhibit toward the environment (Dingemanse et al. 2010; Stamps 2016), as well as in the intra-individual  
28 variability of their behavior across time (Biro and Adriaenssens 2013; Westneat, Wright, and Dingemanse  
29 2015). These respective patterns of personality, plasticity, and predictability represent distinct but often  
30 integrated components of the behavioral reaction norms (RNs) within a population (see **Figure 1**), which are  
31 functions expressing individual-specific behavioral strategies across an environmental gradient (Dingemanse  
32 et al. 2010; McNamara and Leimar 2020). The evolution of such function-valued traits is currently a  
33 central area of research within evolutionary ecology (Gomulkiewicz et al. 2018), which has led to a host

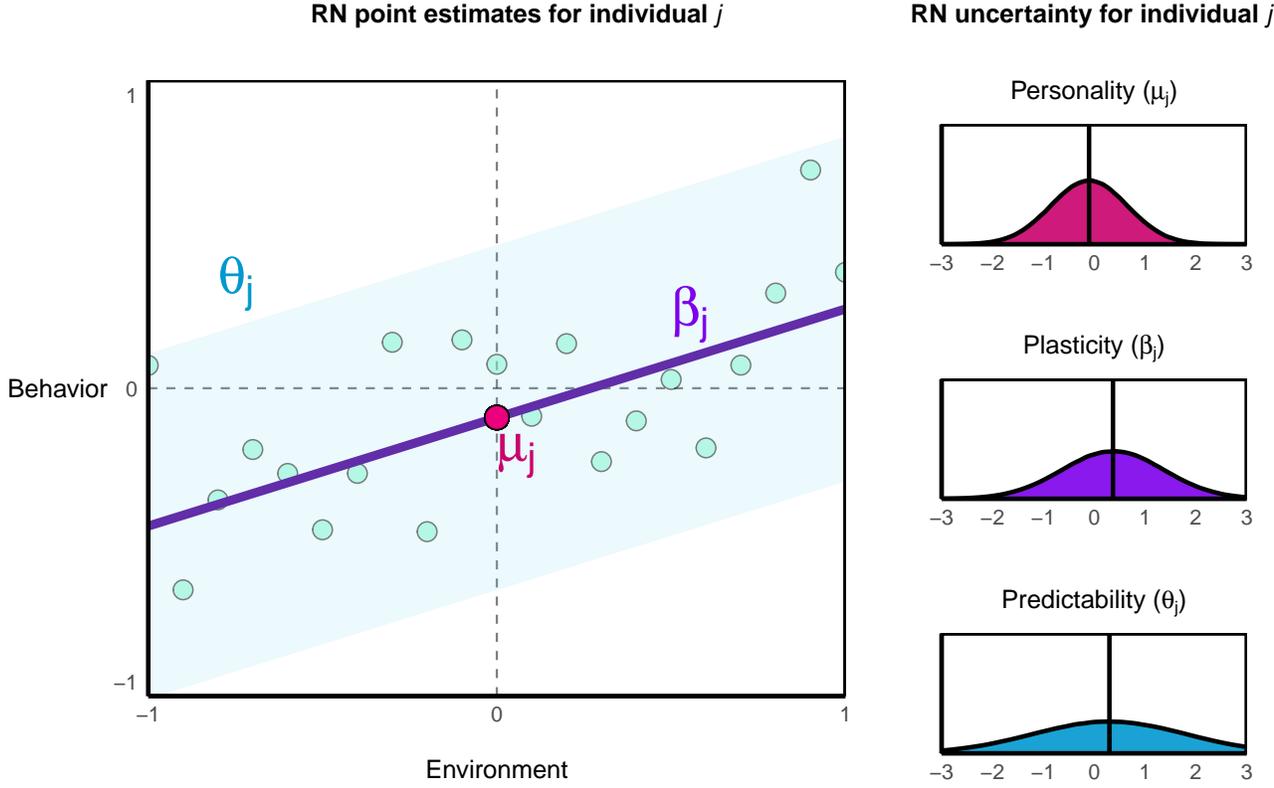

34 of methodological innovations for estimating the RNs of complex traits subject to measurement error  
35 (Dingemanse and Dochtermann 2013; Martin and Jaeggi 2021), as well as the development of a rich theoretical  
36 framework for explaining the adaptive processes maintaining individual variation in RNs within populations  
37 (Dall and Griffith 2014; Sih et al. 2015; Wolf and Weissing 2010). Attention to RNs has also increased in  
38 related fields of inquiry such as personality psychology (Nettle and Penke 2010) and evolutionary anthropology  
39 (Jaeggi et al. 2016), suggesting that an integrative framework for studying the evolution of RNs will benefit  
40 research on individuality more generally.

41 For labile phenotypes such as behavior, hormones, and cognition, the magnitude of repeatable between-  
42 individual variation in measurements is generally modest in comparison to the total phenotypic variation  
43 observed across space and time (Bell, Hankison, and Laskowski 2009; Cauchoux et al. 2018; Fanson and Biro  
44 2015). This is unsurprising, given that these traits are often the primary mechanisms by which organisms can  
45 flexibly respond to ephemeral and stochastic variation in their local environments, such as by up-regulating  
46 circulating testosterone in response to social challenges (Eisenegger, Haushofer, and Fehr 2011), or by  
47 temporarily inducing a fear state in response to odor cues of predation (Mathuru et al. 2012). As such,  
48 single measurements of these phenotypes are poor indicators of the underlying between-individual differences  
49 that are targeted by selection, and tend to instead reflect various sources of within-individual environmental  
50 heterogeneity (Brommer 2013; Dingemanse and Dochtermann 2013). Despite the unfortunate fact that many  
51 empirical studies still confound these distinct sources of trait (co)variation (Niemelä and Dingemanse 2018;  
52 Royauté et al. 2018), the necessity of longitudinal data for studying RNs is increasingly appreciated and  
53 enforced within behavioral ecology (Dingemanse and Wright 2020). With the appropriate application of  
54 generalized mixed-effect models (GLMMs), such repeated measures data can then be used to estimate the  
55 unobserved but statistically identifiable RNs underlying raw trait measurements, thus effectively partitioning  
56 stochastic effects and measurement error from repeatable sources of between-individual variation (Dingemanse  
57 and Dochtermann 2013; Martin and Jaeggi 2021; Nakagawa and Schielzeth 2010; Nussey, Wilson, and  
58 Brommer 2007).

59 GLMMs are a powerful tool not only for estimating RNs from empirical data using random effects, but also  
60 for subsequently modeling the fixed effects of personality, plasticity, and predictability on fitness and other  
61 biological outcomes of interest. Nevertheless, although GLMMs provide a quite robust modeling framework  
62 (Schielzeth et al. 2020), they can only give as much information about RNs and their effects as the model  
63 assumptions and empirical data provided to them. For labile phenotypes like behavior, this means that the  
64 predicted random effect values of RN parameters, also known as best linear unbiased predictors (BLUPs), are  
65 often inferred with non-trivial degrees of statistical uncertainty. The use of BLUP point estimates to predict  
66 outcomes in another response model will, therefore, artificially reduce uncertainty in the estimated effects  
67 of RNs and increase the risk of false positives (see Hadfield et al. 2010 for a detailed treatment). Previous  
68 solutions to this problem have provided effective antidotes to the anti-conservative inference encouraged by  
69 ignoring uncertainty in BLUPs (Houslay and Wilson 2017). However, these solutions also reduce empiricists'  
70 capacity to effectively model the nonlinear effects of RNs on fitness-relevant outcomes, which is necessary for  
71 understanding the degree to which natural selection is actively maintaining or diminishing individual variation  
72 in behavior. The present study therefore introduces a new method to facilitate unbiased estimation of nonlinear  
73 RN effects within a Bayesian GLMM framework. The proposed solution is first motivated through a brief  
74 discussion of current approaches to the misuse of BLUPs and their benefits and limitations. I then formally  
75 introduce the proposed method along with a novel approach to visualizing the effects of multivariate selection  
76 on reaction norms. I also provide R code (R Core Team 2020) and tutorials on the accompanying Github  
77 repository for this manuscript (<https://github.com/Jordan-Scott-Martin/Selection-on-RNs>), demonstrating  
78 how to estimate these models with the Stan statistical programming language (Carpenter et al. 2017). These  
79 tutorials will aid researchers in investigating nonlinear RN effects with their own datasets.

## 80 **2 Current approaches**

81 The basic challenge of modelling RN effects is to effectively account for the uncertainty in RN parameters  
82 (i.e. BLUPs) across all stages of analysis. Variation in phenotypes with low to moderate repeatability is, by  
83 definition, largely explained by factors other than between-individual differences. As a consequence, sampling  
84 designs with modest repeated measurements and uncontrolled environmental variation typically result in  
85 highly uncertain estimation of RNs. Failure to account for the uncertainty of RNs across subsequent stages  
86 of analysis artificially reduces uncertainty in the inferred effects of RNs, as uncertainty in individuals' trait  
87 values necessarily translates into uncertainty about the effects of these trait values, and can thus undesirably  
88 increase the risk of false positives. For this reason, Hadfield et al. (2010) discouraged all future use of

**Figure 1:** A behavioral reaction norm (RN) for individual  $j$  defined across an environmental gradient. The individual's reaction norm is defined by three parameters indicated in the left plot: (i) the RN intercept trait value  $\mu_j$  describing behavioral consistency (i.e. personality) across environments; (ii) the RN slope trait value  $\beta_j$  capturing behavioral plasticity across environments; and (iii) the RN dispersion trait value  $\theta_j$  reflecting behavioral predictability across environments, as indicated by the 95% shaded credible interval (i.e.  $\pm 1.96 * \theta_j$ ). Individuals' true RN parameters will be unknown in empirical research and must be inferred from raw longitudinal measurements (teal circles) across the environmental gradient. These inferences will generally be subject to high degrees of statistical uncertainty, as captured by the posterior distributions of each RN parameter shown on the right. RN point estimates (BLUPs) taken from these posterior distributions, such as the mean values indicated by the black vertical lines, ignore this uncertainty and provide misleading confidence in the shape of an individuals' behavioral strategy. For example, it can be seen that there is a wide range of possible values for individual  $j$ 's parameters with similar degrees of posterior support, particularly for the highly uncertain predictability trait value. As has been previously emphasized in the literature, failure to account for this uncertainty around point estimates can lead to anti-conservative inference and an increased risk of false positives. See the main text for further discussion.

89 BLUP point estimates in evolutionary ecology, so as to prevent the proliferation of misleading findings in the  
 90 literature. Nevertheless, because the theoretical significance of RNs is not diminished by the difficulty of  
 91 appropriately modeling their effects, many behavioral ecologists without clear alternative solutions continued  
 92 to misuse point estimates of BLUPs in their research. In response, Houslay and Wilson (2017) provided a  
 93 detailed overview of appropriate strategies for tackling this challenge, emphasizing that multivariate GLMMs  
 94 with covarying random effects can be used to effectively account for uncertainty in RNs across multiple  
 95 response models. Despite these repeated cautionary notes, some researchers still continue to utilize BLUP  
 96 point estimates (e.g. Dingemanse et al. 2020) or raw data (e.g. Brehm et al. 2019) for testing RN effects,  
 97 even while acknowledging the work of Hadfield et al. (2010) and Houslay and Wilson (2017). This likely  
 98 reflects the fact that the random effects models proposed by Houslay and Wilson (2017) do not readily  
 99 extend to a variety of more complex RN effects that cannot be straightforwardly derived from random effect  
 100 covariances and correlations. This section briefly reviews current solutions for the misuse of BLUPs and  
 101 discusses their benefits and limitations.

## 102 2.1 Multivariate GLMMs with covarying random effects

103 Popular GLMM software such as the “lme4” R package (Bates et al. 2014) do not readily address multivariate,  
 104 integrated phenotypes. As a consequence, researchers are often motivated to (i) estimate RNs from a  
 105 univariate response model of a relevant behavior, and (ii) subsequently enter BLUP point estimates of these  
 106 RNs as covariates in another response model. Fortunately, the risk engendered by this approach can be readily  
 107 overcome by specifying a multivariate GLMM that simultaneously accounts for uncertainty in behavioral  
 108 BLUPs and their associations with other responses. Houslay and Wilson (2017) demonstrate how this can be  
 109 accomplished with random effect correlations or covariances for phenotypic and quantitative genetic studies,  
 110 using both frequentist and Bayesian software.

111 The multivariate GLMMs proposed by Houslay and Wilson (2017) are an extremely valuable tool for  
 112 behavioral ecologists interested in RNs and integrated phenotypes. These models provide desirable flexibility  
 113 for addressing a variety of questions beyond simply quantifying random effect variances and covariances,  
 114 although this is on its own quite an important task. As any student of multivariate statistics is well aware,  
 115 trait covariance matrices can be readily transformed to provide a veritable treasure chest of biological insights  
 116 (Blows 2007), such as identifying trajectories of phenotypic conservation and divergence among closely  
 117 related populations (Royauté, Hedrick, and Dochtermann 2020), discovering latent behavioral characters and  
 118 networks causing covariance among multiple traits (Araya-Ajoy and Dingemanse 2014; Martin et al. 2019),  
 119 and calculating linear selection differentials and genetic responses to selection (Stinchcombe, Simonsen, and  
 120 Blows 2014). Thus, this method can be used to accomplish many empirical goals with relative ease.

121 Nevertheless, there are important cases where further information is desired that cannot be derived from  
 122 random effect covariation alone, limiting the utility of these models for explaining the effects of RNs on  
 123 evolutionarily relevant outcomes. This is why fixed effects remain important for testing evolutionary ecological  
 124 theory, because we often want to directly parameterize specific functional relationships between traits, as well  
 125 as to specify the direction of these effects. In other words, we often want to know whether a behavior affects  
 126 another measure in a specific, potentially nonlinear manner, and perhaps in interaction with other traits  
 127 or states, rather than merely asking whether the trait and the outcome are linearly associated through any  
 128 number of possible causal pathways in either direction. This issue is not specific to the models proposed by  
 129 Houslay and Wilson (2017), but is rather a limitation of variance-partitioning models more generally, which  
 130 tend to trade off explanatory power and causal insight for accurate description and *in situ* prediction (Briley  
 131 et al. 2019; Hadfield and Thomson 2017; Okasha and Otsuka 2020).

132 A particular concern is that testing adaptive theory of individual variation often requires evaluating nonlinear  
 133 selection on behavioral RNs (**Figure 2**). In general, these nonlinear effects cannot be accurately estimated  
 134 by random effect covariances, as covariance is by definition a measure of linear dependency and thus does not  
 135 capture nonlinear dependencies among measures. However, it is straightforward to capture these patterns  
 136 using fixed quadratic and interaction effects in a parametric fitness model (Lande and Arnold 1983). For  
 137 example, if the population RN is at an evolutionary equilibrium, so that RN variation is non-adaptive within  
 138 the population and results from processes such as mutation-selection balance or developmental noise (e.g.  
 139 Bierbach, Laskowski, and Wolf 2017; Tooby and Cosmides 1990), then we should expect to find evidence of  
 140 stabilizing selection around the population average RN parameters. In the absence of correlational selection,  
 141 this would be observed in a Lande-Arnold selection analysis as null or weak linear effects and negative  
 142 quadratic effects (Stinchcombe et al. 2008), assuming the population had not been recently displaced from a  
 143 fitness peak by non-adaptive processes. Alternatively, strong disruptive selection, potentially indicative of

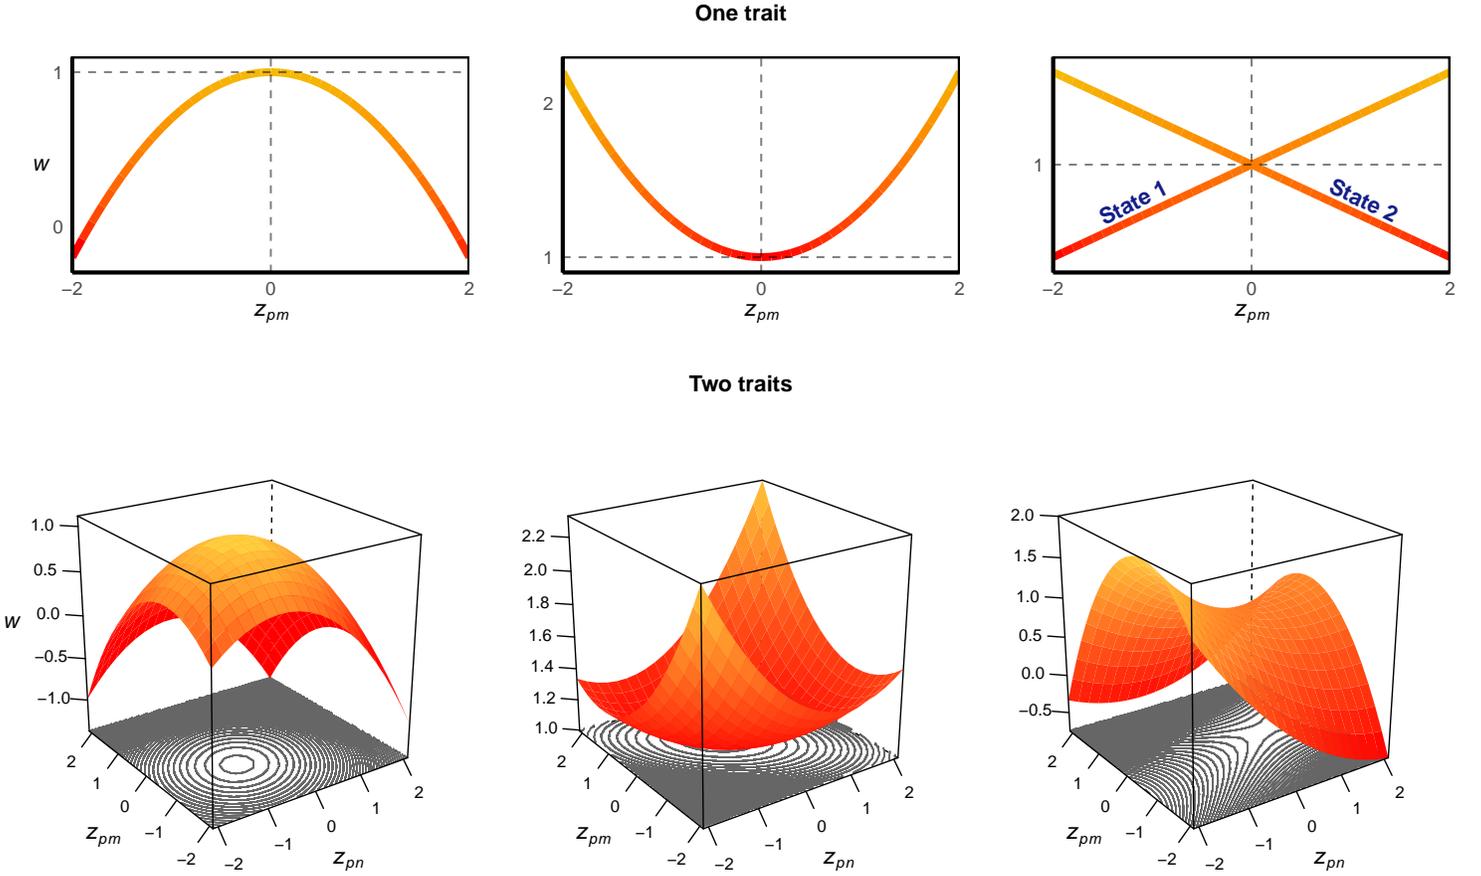

144 ongoing behaviorally-mediated speciation (Wolf and Weissing 2012), would be expected to surface as the  
 145 opposite pattern—null or weak linear effects with positive quadratic effects.

146 When individual variation is adaptive and maintained through balancing selection caused by spatially and/or  
 147 temporally varying fitness effects (e.g. Gurven et al. 2014; Le Cœur et al. 2015), interaction effects will  
 148 be expected between local ecological conditions (e.g. season, population density, resource abundance) and  
 149 individuals’ RN parameters (Wright et al. 2019). Similar considerations apply to social contexts addressed  
 150 by evolutionary game theory, in which frequency-dependent fitness functions, such as cooperative strategies  
 151 with diminishing returns or threshold effects as a function of partners’ strategies (McNamara and Leimar  
 152 2020), will be observed through interactive selection effects (Araya-Ajoy, Westneat, and Wright 2020; Martin  
 153 and Jaeggi 2021; Queller 2011). When adaptive individual variation is maintained through state-dependent  
 154 calibration or feedback processes (e.g. von Rueden, Lukaszewski, and Gurven 2015; Sih et al. 2015), then  
 155 phenotypes should also interact with state variables to determine fitness outcomes. Adaptive behavioral  
 156 syndromes may further evolve through correlational selection for specific RN parameter combinations. Cichlid  
 157 *Pelvicachromis pulcher* females’ mating preferences, for example, select for males with high levels of both  
 158 personality and predictability in aggressiveness (Scherer, Kuhnhardt, and Schuett 2018). When RNs are  
 159 under such correlational selection, interaction effects are expected between RN parameters on fitness (Blows  
 160 2003). Of course, these considerations also apply to a host of RN effects on outcomes other than fitness, such  
 161 as the exponential effects of personality in activity level and anxiety on seed removal and dispersal among  
 162 small mammals (Brehm et al. 2019). In all such cases, one would not detect these theoretically pertinent  
 163 relationships using linear covariances among random effects, but must instead directly specify fixed quadratic  
 164 and interactive effects caused by behavioral RNs. A variety of more complex fitness surfaces can also be  
 165 captured through the combination of these quadratic and interaction effects (Phillips and Arnold 1989), or  
 166 higher term polynomials, as shown in **Figure 2** for a bivariate analysis.

167 A potential solution to this challenge is to model the squared and product values of raw measurements as  
 168 additional responses with covarying random effects, which can subsequently be used to calculate nonlinear  
 169 selection gradients (Dingemans, Araya-Ajoy, and Westneat 2021). However, this approach does not differenti-  
 170 ate between the fitness effects of personality, plasticity, and predictability, and it does not appropriately  
 171 partition between- and within-individual (co)variation in non-Gaussian measurements. To calculate nonlinear  
 172 selection gradients for non-Gaussian responses, expected trait values should be first estimated on a latent  
 173 linear scale, through the use of an appropriate GLMM link function, before being squared or multiplied  
 174 together. This ensures that nonlinear mean and variance effects are correctly predicted on the original data  
 175 scale (Nelder and Wedderburn 1972).

## 176 2.2 Two-stage analyses

177 Another solution to the challenges posed by the random effects method is to instead (i) estimate BLUP  
 178 posteriors in a Bayesian random effects model, and then (ii) estimate a separate model with fixed RN effects,  
 179 running the analysis repeatedly over the posterior distribution of BLUPs estimated in the first model. While  
 180 this approach technically carries the uncertainty in RNs forward, thus avoiding the undesirable consequences  
 181 of point estimates, it can nevertheless result in downwardly biased estimates of the RN fixed effects, as  
 182 Dingemans et al. (2020) observed in supplementary simulations. Although these authors did not provide an  
 183 explanation for the observed bias, it can be attributed to a more general statistical phenomenon known as  
 184 attenuation bias, in which independent measurement error in a predictor variable causes downward bias in  
 185 its association with an outcome measure (Adolph and Hardin 2007; Spearman 1904). This is caused by the  
 186 BLUPs in the initial model being estimated independently of the RN effects on the outcome of interest, so  
 187 that the estimated uncertainty in BLUPs is by design statistically independent of uncertainty in the RN  
 188 effects estimated in the second stage of the analysis. This does not, however, make the use of BLUP point  
 189 estimates any less risky or more desirable, but is simply an artifact of not simultaneously accounting for both  
 190 sources of uncertainty in the same model. It is important to remember that BLUPs and RNs are latent,  
 191 statistical inferences, not directly measured trait values or mere averages of raw trait values, and as such are  
 192 particularly sensitive to correct model specification (Hadfield et al. 2010; Postma 2006). A related alternative  
 193 solution is to handle attenuation bias by adjusting selection coefficients on raw trait values with repeatability  
 194 estimates, rather than directly using BLUPs in the fitness model (Dingemans, Araya-Ajoy, and Westneat  
 195 2021). However, this approach does not provide a means of differentiating nonlinear selection on personality,  
 196 plasticity and predictability, nor does it generalize to non-Gaussian measurements where repeatability is best  
 197 expressed on a transformed linear scale due to non-linear mean and variance effects on the original scale.

**Figure 2:** Nonlinear selection surfaces for behavioral RNs. Adaptiveness is indicated by the color of the line or surface, with red indicating lower relative fitness ( $w$ ) and gold indicating higher relative fitness.

**Top row.** Patterns of nonlinear selection on a single behavioral RN parameter  $z_{pm}$ , which also apply to selection on multiple traits in the absence of correlational selection between traits. Dashed lines intercept the expected population-level trait value and relative fitness at  $(z_{pm} = 0, w = 1)$ . *Left panel:* stabilizing selection on trait values, which maintains the population average trait value at an evolutionary equilibrium and reduces individual variation. *Middle panel:* disruptive selection, which increases the frequency of extreme trait values and increases individual variation as a consequence. *Right panel:* balancing selection, in which the fitness consequences of a trait value vary across different states, causing the maintenance of individual variation across multiple selection events. States refer to any factors that modulate the fitness consequences of a behavior, such as differing spatial and/or temporal contexts, population densities, or frequencies of social partner strategies. States may also be endogenous factors that determine whether it is adaptive to express a particular RN trait value, such as the effects of body size and condition on the fitness consequences of boldness and aggression.

**Bottom row.** Patterns of nonlinear selection on two behavioral RN parameters  $z_{pm}$  and  $z_{pn}$ . Due to the presence of correlational selection, the adaptiveness of any trait value for parameter  $m$  is contingent on the trait value for parameter  $n$  (and vice versa). *Left panel:* a dome-shaped selection surface, where a combination of slightly negative parameters has the highest fitness. *Middle panel:* a bowl-shaped selection surface, with the most adaptive phenotypes combining extremely high or low trait values in both parameters. *Right panel:* a saddle-shaped selection surface, where phenotypes combining moderate trait values for  $m$  and extremely low trait values for  $n$  achieve the highest relative fitness.

### 198 3 A novel solution

199 Given the limitations of relying solely on covarying random effects, behavioral ecologists stand to benefit  
 200 from adding an additional modeling approach to their toolkit, one capable of directly estimating nonlinear  
 201 RN effects of arbitrary complexity. Here I propose a novel solution that is a straightforward extension of  
 202 Houslay and Wilson (2017) ‘s previous work: Bayesian multi-response GLMMs in which individuals’ RNs  
 203 are simultaneously treated as random effects on their observed behaviors as well as fixed effects on outcome  
 204 measures of interest (e.g. survival and reproduction, habitat choice, performance in an experimental task,  
 205 etc.). In this section, this basic modelling approach is formally introduced, along with various extensions  
 206 of interest for specific empirical scenarios. I also end by proposing a novel and straightforward method for  
 207 visualizing the within-generation effects of multivariate selection on reaction norms.

#### 208 3.1 Multivariate GLMMs for nonlinear selection on RNs

209 Our goal in overcoming the limitations of previous approaches is to specify a GLMM with one response model  
 210 estimating RN parameters of a relevant behavior, as well as another response model that estimates the effects  
 211 of these RN parameters on a fitness-relevant measure. To enhance comprehension, the RN response model is  
 212 first considered in isolation before being integrated into a single multi-response model below.

##### 213 3.1.1 Reaction norm response model

214 To model the RN parameters  $\mathbf{z}_p$  for a repeatedly measured behavior  $\mathbf{z}$  across an environmental gradient  $\mathbf{x}$ ,  
 215 we specify a GLMM for observation  $i$  of individual  $j$  such that

$$\begin{aligned} z_{ij} &\sim f(\eta_{ij}, \theta_{ij}) & (1.1) \\ g_\eta(\eta_{ij}) &= \mu_0 + \mu_j + (\beta_1 + \beta_j) x_{ij} \\ g_\theta(\theta_{ij}) &= \theta_0 + \theta_j \\ \mathbf{z}_p &= [\boldsymbol{\mu} \quad \boldsymbol{\beta} \quad \boldsymbol{\theta}]' \sim \text{MVNormal}(\mathbf{0}, \mathbf{P}) \end{aligned}$$

216 Bold values are used to distinguish vectors and matrices from scalars and primes  $'$  are used to indicate the  
 217 transpose operation. Individuals’ traits values are specified as being generated by some probability density  
 218 function  $f$  with corresponding location  $\boldsymbol{\eta}$  and dispersion  $\boldsymbol{\theta}$  parameters, such as the means and standard  
 219 deviations of normal distributions or the means and shape parameters of gamma, negative binomial, and  
 220 beta distributions. For GLMMs, these nonlinear parameters are modelled on a latent linear scale using link  
 221 functions  $g_\eta$  and  $g_\theta$  (e.g. identity, log, logistic, or reciprocal transformations). We therefore refer to  $g_\eta(\eta_{ij})$   
 222 and  $g_\theta(\theta_{ij})$  as the linear predictors for the respective location and dispersion parameters of observation  $i$  on  
 223 individual  $j$ .

224 Typically, personality and plasticity are modelled through the linear predictor of the location parameters,  
 225 capturing variation in expected behavior (i.e. predicted behavior averaged over dispersion). This is accom-  
 226 plished through the estimation of random intercept  $\mu_j$  and random slope  $\beta_j$  for individual  $j$ , which are  
 227 expressed as deviations from the population-average intercept  $\mu_0$  and slope  $\beta_1$ . These parameters correspond  
 228 to the elevation and slope of the individual’s behavioral RN. We assume that environmental exposures are  
 229 randomized across individuals, so that there is no need to within-individual center the covariate used for  
 230 scaling RN slopes (van de Pol and Wright 2009). Predictability is modelled through a random intercept  
 231 effect  $\theta_j$  on the dispersion parameters, deviating from the population-average dispersion  $\theta_0$ , which captures  
 232 individual-specific variability independent of the linear predictor. The effect of each parameter in  $\mathbf{z}_p$  on  
 233 the shape of an individual’s RN can be seen in **Figure 1**. For simplicity, we ignore the possibility that  
 234 individuals may also exhibit plasticity in their predictability as a function of the environment, although this  
 235 could be readily estimated, along with other fixed and random effects. For distributions without an explicit  
 236 dispersion parameter, such as Poisson or binomial distributions, individual differences in predictability cannot  
 237 be directly modelled in this way. However, this limitation can be easily avoided by using a closely related  
 238 distribution accounting for overdispersion, such as the negative binomial and beta binomial distributions.

239 The associations among RN parameters are captured by the trait covariance matrix  $\mathbf{P}$ . Note that covariance  
 240 and correlation matrices can always be translated to one another by  $\mathbf{P} = \mathbf{SRS}$ , where  $\mathbf{S}$  is a diagonal matrix  
 241 with standard deviations and  $\mathbf{R}$  is a correlation matrix. This identity is often useful for efficiently estimating  
 242 Bayesian GLMMs by separating out the scale and association parameters among random effects. We therefore  
 243 substitute  $\mathbf{SRS}$  for  $\mathbf{P}$  in subsequent formula.

244 **3.1.2 Multi-response model for selection analysis**

245 Our goal is to now specify a single multi-response model that estimates (Eq 1.1) while also estimating the  
 246 effects of RN parameters  $\mathbf{z}_p$  on fitness. Given that researchers will often lack repeated measures of fitness or  
 247 fitness-proxies (e.g. bodily condition, clutch size, mate choice), the presented models assume that a single  
 248 fitness measure is available per individual, although this assumption can be relaxed by including additional  
 249 random effects to account for unobserved heterogeneity in repeated fitness measures. For simplicity, we also  
 250 begin by assuming that the fitness measure can be effectively described by a Gaussian distribution, which  
 251 simplifies the estimation of selection gradients and differentials below. As is appropriate for modelling relative  
 252 fitness (Lande and Arnold 1983),  $w$  is mean-scaled so that  $w_j = W_j/\bar{W}$  where  $\bar{W}$  is the mean absolute fitness  
 253 across individuals. For notational clarity, we now introduce superscripts ( $z$ ) to distinguish parameters that  
 254 are specific to the  $z$  behavioral response model from those in the  $w$  fitness response model.

$$\begin{aligned}
 z_{ij} &\sim f\left(\eta_{ij}^{(z)}, \theta_{ij}^{(z)}\right) & (1.2) \\
 g_\eta\left(\eta_{ij}^{(z)}\right) &= \mu_0^{(z)} + \mu_j^{(z)} + \left(\beta_1^{(z)} + \beta_j^{(z)}\right) x_{ij} \\
 g_\theta\left(\theta_{ij}^{(z)}\right) &= \theta_0^{(z)} + \theta_j^{(z)} \\
 \mathbf{z}_p &= [\boldsymbol{\mu}^{(z)} \quad \boldsymbol{\beta}^{(z)} \quad \boldsymbol{\theta}^{(z)}]' \sim \text{MVNormal}(\mathbf{0}, \mathbf{SRS})
 \end{aligned}$$

$$\begin{aligned}
 w_j &\sim \text{Normal}(\mu_j, \sigma_j) \\
 \mu_j &= \mu_0 + \beta_1 \left(\mu_j^{(z)}\right) + \beta_2 \left(\beta_j^{(z)}\right) + \beta_3 \left(\theta_j^{(z)}\right) \\
 &+ \beta_4 \left(\mu_j^{(z)} \mu_j^{(z)}\right) + \beta_5 \left(\beta_j^{(z)} \beta_j^{(z)}\right) + \beta_6 \left(\theta_j^{(z)} \theta_j^{(z)}\right) \\
 &+ \beta_7 \left(\mu_j^{(z)} \beta_j^{(z)}\right) + \beta_8 \left(\mu_j^{(z)} \theta_j^{(z)}\right) + \beta_9 \left(\beta_j^{(z)} \theta_j^{(z)}\right)
 \end{aligned}$$

255 Readers familiar with structural equation modelling (Araya-Ajoy and Dingemanse 2014; Martin et al. 2019)  
 256 may note that each RN parameter in this model can be conceptualized as an exogenous latent variable, with  
 257 its loading on trait  $z$  fixed to 1, thus scaling the zero-centered latent variable, and its loadings on trait  $w$   
 258 estimated with the regression coefficients. These latent variables separate out the portions of variance in trait  
 259  $\mathbf{z}$  due to each latent RN parameter and, therefore, isolate distinct RN effects on fitness from all other sources  
 260 of non-repeatable variation in the raw trait values. The proposed model can also be conceptualized as an  
 261 extension of the so-called ‘errors-in-variables’ models discussed by Dingemanse, Araya-Ajoy, and Westneat  
 262 (2021), which do not disentangle repeatable variation in raw measurements due to personality, plasticity, and  
 263 predictability. This multi-response GLMM thus provides a flexible and intuitive means of integrating the  
 264 benefits as well as overcoming the limitations of multiple previously suggested statistical approaches. It is  
 265 also important to note that the proposed model can always be simplified to facilitate studies of selection  
 266 on individual RN parameters, should researchers lack sufficient repeated samples or environmental data to  
 267 simultaneously address personality, plasticity, and predictability.

268 When this quadratic regression model effectively approximates the individual selection surface (Lande and  
 269 Arnold 1983; Phillips and Arnold 1989),  $\boldsymbol{\beta} = [\beta_1, \beta_2, \beta_3]$  indicates the expected direction and magnitude of  
 270 unconstrained adaptation in the average population RN values, which are also known as directional selection  
 271 gradients. Nonlinear effects are instead captured by  $\gamma_{\mu,\mu} = \beta_4 * 2$ ,  $\gamma_{\beta,\beta} = \beta_5 * 2$ , and  $\gamma_{\theta,\theta} = \beta_6 * 2$ , which  
 272 indicate convex or concave curvature in the selection surfaces of RN parameters (Stinchcombe et al. 2008),  
 273 and  $\gamma_{\mu,\beta} = \beta_7$ ,  $\gamma_{\mu,\theta} = \beta_8$ , and  $\gamma_{\beta,\theta} = \beta_9$ , which indicate further curvature due to the presence of correlational  
 274 selection between trait pairs. The regression coefficients capturing nonlinear curvature in the selection surface  
 275 can then be grouped into a matrix  $\boldsymbol{\gamma}$  of quadratic selection gradients and the fitness model can be simplified  
 276 to matrix notation for individual  $j$  such that

$$\begin{aligned}
 \mu_j &= \mu_0 + \boldsymbol{\beta}' \mathbf{z}_{pj} + \frac{1}{2} \mathbf{z}'_{pj} \boldsymbol{\gamma} \mathbf{z}_{pj} & (1.3) \\
 \boldsymbol{\gamma} &= \begin{pmatrix} \gamma_{\mu,\mu} & \gamma_{\mu,\beta} & \gamma_{\mu,\theta} \\ \gamma_{\beta,\mu} & \gamma_{\beta,\beta} & \gamma_{\beta,\theta} \\ \gamma_{\theta,\mu} & \gamma_{\theta,\beta} & \gamma_{\theta,\theta} \end{pmatrix}
 \end{aligned}$$

277 If one desires to express gradients in standardized units for effect size comparison, then  $\mathbf{z}_{\mathbf{p}j}^* = \mathbf{z}_{\mathbf{p}j} \oslash \text{diag}(\mathbf{S})$   
 278 can instead be specified in the fitness response model, where the Hadamard division  $\oslash$  indicates element-wise  
 279 division of each parameter by its standard deviation, which are contained on the diagonal of the  $\mathbf{S}$  matrix.  
 280 The selection model can also be extended to account for various kinds of balancing selection (see **Figure 2**)  
 281 by including additional interaction effects for the relevant state variables. For example,  $\beta_I(\mu_j^{(z)} * N)$  could be  
 282 estimated to assess the presence of density-dependent selection on personality across differing population  
 283 sizes  $N$ .

284 It is common in selection analyses to estimate linear and nonlinear gradients on observed trait values  $\mathbf{z}$ ,  
 285 rather than directly on RN parameters  $\mathbf{z}_{\mathbf{p}}$  as proposed here. However, it is ultimately the repeatable  
 286 individual variation in a phenotype that is available to selection, with all other trait variation effectively  
 287 representing measurement error from the perspective of evolutionary inference at the population level (Martin  
 288 and Jaeggi 2021). Thus, it is genetically encoded behavioral strategies (i.e. RNs) that are adapted within  
 289 a population, rather than the specific actions animals are observed taking in any particular measurement  
 290 context (McNamara and Leimar 2020). Moreover, when RN parameters are not completely integrated, so  
 291 that  $\mathbf{R} \neq \mathbf{1}$ , selection can further act on independent variation in each element of  $\mathbf{z}_{\mathbf{p}}$ , leading to distinct  
 292 changes in the population RN intercept, slope, and dispersion within and across generations. These adaptive  
 293 processes will be confounded when solely considering selection on observed trait values  $\mathbf{z}$ . The global effects of  
 294 RN parameter selection on the shape of the population RN function can also be straightforwardly estimated  
 295 and visualized using methods developed further below.

### 296 3.1.3 Fully Bayesian inference

297 To the best knowledge of the author, the proposed multi-response model for RN selection analysis cannot  
 298 be straightforwardly estimated with mainstream statistical software. This does not, however, reflect any  
 299 fundamental issue with its parameterization or interpretation, but rather pragmatic limitations of the  
 300 estimators and/or syntax used in these software, which generally do not allow the same latent parameters to  
 301 be specified across different GLMM response models. Fortunately, the Stan statistical programming language  
 302 (Carpenter et al. 2017), which relies on cutting-edge and computationally efficient Markov Chain Monte  
 303 Carlo (MCMC) algorithms, provides exceptional flexibility for specifying and straightforwardly estimating  
 304 such atypical GLMMs within a Bayesian framework. Researchers unfamiliar with the general benefits of fully  
 305 Bayesian inference are encouraged to see McElreath (2020) for detailed discussion, as well as Gelman et al.  
 306 (2020) for helpful tips on developing an effective Bayesian workflow for data analysis. A brief review of some  
 307 fundamentals will facilitate robust estimation and hypothesis testing with the proposed model.

To estimate Eq 1.2 within a Bayesian framework, we simply need to specify prior distributions for all the  
 population-level parameters, which are transformed within the model to derive the individual-level RN  
 parameters during model estimation.

$$\mu_0^{(z)}, \beta_1^{(z)}, \theta_0^{(z)}, \mathbf{S}, \mathbf{R}, \mu_0, \sigma, \beta_1, \dots, \beta_9 \sim \mathbf{f}(\Phi)$$

308 As above,  $\mathbf{f}$  are probability density functions for each parameter and  $\Phi$  are the corresponding distributional  
 309 parameters for all priors. Although it is common for ecology methods papers to use and/or recommend  
 310 using highly diffuse or flat priors (e.g. Houslay and Wilson 2017; Villemereuil et al. 2016), it is also well  
 311 established within the statistics literature that weakly informative, regularizing priors—which slightly pull  
 312 parameters toward null values and provide low prior probability to extreme effect sizes—facilitate more robust  
 313 inferences and should generally be preferred over flat priors whenever possible (Gelman and Tuerlinckx 2000;  
 314 McElreath 2020; Lemoine 2019). This does not require that one has access to a relevant meta-analysis or is in  
 315 a position to make strong a priori assumptions about the true effect size (cf. Ellison 2004). Rather, one can  
 316 simply use general-purpose, conservative priors as a means of increasing the generalizability and robustness of  
 317 their findings, even in a state of relative ignorance about the true effect size. For most GLMMs, priors such  
 318 as  $\mu, \beta \sim \text{Normal}(0, 1)$ ,  $\text{diag}(\mathbf{S}), \sigma \sim \text{Exponential}(1)$ , and  $\mathbf{R} \sim \text{LKJ}(2)$  provide effective weakly regularizing  
 319 priors. See Lemoine (2019) for more detailed discussion and recommendations in ecological research.

By specifying priors in the model, all parameters can subsequently be estimated as posterior distributions.  
 For example,  $\mathbf{z}_{\mathbf{p}}$  will no longer be estimated with BLUP point estimates  $\hat{\mu}_j^{(z)}$ ,  $\hat{\beta}_j^{(z)}$ , and  $\hat{\theta}_j^{(z)}$ , but will instead  
 be estimated with probability distributions capturing all of the statistical uncertainty in the BLUPs

$$\Pr\left(\mu_j^{(z)} \mid \mathbf{x}, \mathbf{z}, \mathbf{w}, \dots, \Phi\right), \quad \Pr\left(\beta_j^{(z)} \mid \mathbf{x}, \mathbf{z}, \mathbf{w}, \dots, \Phi\right), \quad \Pr\left(\theta_j^{(z)} \mid \mathbf{x}, \mathbf{z}, \mathbf{w}, \dots, \Phi\right)$$

These posterior distributions are conditional on the observed measures  $(\mathbf{x}, \mathbf{z}, \mathbf{w})$  and all other model parameters  
 and priors ( $\dots\Phi$ ). Given that all statistical uncertainty is captured in these and other posterior distributions,

the proposed multi-response model (Eq 1.2) provides nearly unlimited flexibility for direct forms of hypothesis testing. For example, to quantify our confidence that positive correlational selection occurs for plasticity and predictability, we simply need to manipulate the relevant posteriors to calculate

$$\Pr(\gamma_{\beta,\theta} > 0 \mid \mathbf{x}, \mathbf{z}, \mathbf{w}, \dots, \Phi)$$

When posterior distributions are estimated with Markov Chain Monte Carlo (MCMC), this value can be quantified by assessing this inequality across the relevant vectors of posterior samples and calculating the proportion of samples for which it is satisfied. Similarly, if we want to quantify our confidence that there is greater positive directional selection on personality than plasticity, we can calculate

$$\Pr(\beta_{\mu} > \beta_{\beta} \mid \mathbf{x}, \mathbf{z}, \mathbf{w}, \dots, \Phi)$$

One could similarly perform a direct hypothesis test of a more robust null hypothesis than is typically considered, given that true effect sizes are almost never exactly zero in reality (Amrhein, Trafimow, and Greenland 2019; Meehl 1978; Gelman and Carlin 2017). Instead, a direct test of a null hypothesis can provide the probability that an effect is of a biologically trivial magnitude (e.g.  $< |0.1|$  for a standardized predictor). For instance, considering the correlation among personality and predictability in the  $\mathbf{R}$  correlation matrix

$$\Pr(-0.1 < \mathbf{R}_{\mu,\theta} < 0.1 \mid \mathbf{x}, \mathbf{z}, \mathbf{w}, \dots, \Phi)$$

320 Note that these tests are *not* indirect null hypothesis tests, which give the probability of observing the data  
 321 under the assumption that a null hypothesis is true. Instead, these are direct tests of biologically substantive  
 322 hypotheses given the observed data, the evaluation of which is generally the primary goal of scientific research.  
 323 As such, intuitive interpretation can be made of the posterior probabilities, so that values closer to 1 indicate  
 324 greater support for the tested hypotheses and values closer to 0 indicate stronger support for the opposite  
 325 hypotheses. These Bayesian hypothesis tests help to avoid many common misinterpretations of classical  
 326 tests, such as interpreting confidence intervals as reflecting the probable range of the true effect, interpreting  
 327  $P$ -values as providing the probability of the null hypothesis being true, or interpreting the rejection of a null  
 328 hypothesis test as being indicative of the substantive (“alternative”) hypothesis being correct (Greenland  
 329 et al. 2016; McElreath 2020; McShane et al. 2019). Furthermore, these Bayesian posteriors can be easily  
 330 manipulated to address a variety of questions which may not be easily specified directly in a statistical model.  
 331 This provides theoretically important benefits such as being able to easily quantify uncertainty in and perform  
 332 direct hypothesis tests on derived quantities such as selection differentials,  $R^2$  values, and repeatabilities.

### 333 3.1.4 Non-Gaussian fitness measures

334 Despite the expected robustness of LMMs to violations of distributional assumptions, any particular study  
 335 will be at a non-trivial risk of inferential bias when applying a linear fitness model to outcomes that are clearly  
 336 better described by a non-Gaussian distribution (Schielzeth et al. 2020). Some common non-Gaussian data  
 337 types used for fitness-proxies include dichotomous measures of survival or mating success, counts of offspring  
 338 fledged or surviving to adulthood, and various forms of zero-bounded continuous performance measures such  
 339 as growth rate or dispersal distance. When considering RN effects on other biologically relevant outcomes,  
 340 there are of course a variety of non-Gaussian measures which may be similarly employed, such as categorical,  
 341 mutually exclusive choices or reaction times in cognitive tasks, proportional measures of time spent in an  
 342 activity, and so on. In all such cases, researchers will benefit from more reliable inferences and model  
 343 predictions if they try to accurately describe the data generating process with an appropriate non-Gaussian  
 344 distribution, rather than attempting to pigeonhole their analysis into a linear model. Fortunately, the Stan  
 345 statistical programming language provides a plethora of possible distributions for GLMM likelihood functions,  
 346 as well as the capacity to specify any custom likelihood functions of interest. To account for non-Gaussian  
 347 fitness measure  $W$ , we update the fitness model in Eq 1.2 with a generalized distributional function and link  
 348 transformation.

$$\begin{aligned}
 z_{ij} &\sim f\left(\eta_{ij}^{(z)}, \theta_{ij}^{(z)}\right) \\
 g_{\eta}^{(z)}\left(\eta_{ij}^{(z)}\right) &= \mu_0^{(z)} + \mu_j^{(z)} + \left(\beta_1^{(z)} + \beta_j^{(z)}\right) x_{ij} \\
 g_{\theta}^{(z)}\left(\theta_{ij}^{(z)}\right) &= \theta_0^{(z)} + \theta_j^{(z)} \\
 \mathbf{z}_{\mathbf{p}} &= \left[\boldsymbol{\mu}^{(z)} \quad \boldsymbol{\beta}^{(z)} \quad \boldsymbol{\theta}^{(z)}\right]' \sim \text{MVNormal}\left(\mathbf{0}, \mathbf{SRS}\right)
 \end{aligned} \tag{2}$$

$$\begin{aligned}
 W_j &\sim f\left(\eta_j, \theta\right) \\
 g_{\eta}\left(\eta_j\right) &= \mu_0 + \beta_1\left(\mu_j^{(z)}\right) + \beta_2\left(\beta_j^{(z)}\right) + \beta_3\left(\theta_j^{(z)}\right) \\
 &+ \beta_4\left(\mu_j^{(z)} \mu_j^{(z)}\right) + \beta_5\left(\beta_j^{(z)} \beta_j^{(z)}\right) + \beta_6\left(\theta_j^{(z)} \theta_j^{(z)}\right) \\
 &+ \beta_7\left(\mu_j^{(z)} \beta_j^{(z)}\right) + \beta_8\left(\mu_j^{(z)} \theta_j^{(z)}\right) + \beta_9\left(\beta_j^{(z)} \theta_j^{(z)}\right) \\
 \mu_0^{(z)}, \beta_1^{(z)}, \theta_0^{(z)}, \mathbf{S}, \mathbf{R}, \mu_0, \theta, \beta_1, \dots, \beta_9 &\sim \mathbf{f}\left(\boldsymbol{\Phi}\right)
 \end{aligned}$$

349 Notation follows as above, with priors now specified directly in the model formula. Note that because we do  
 350 not predict the fitness dispersion parameter  $\theta$  with individual-level fixed or random effects, there is no need  
 351 to introduce a linear predictor and corresponding link function. While it was straightforward to translate  
 352 regression coefficients to selection gradients in the Gaussian fitness model, the link function introduced in  
 353 the non-Gaussian model complicates matters. However, as discussed by Morrissey and Sakrejda (2013),  
 354 appropriate gradients can nonetheless be estimated manually using partial derivative functions implemented  
 355 in base R. In particular,

$$\begin{aligned}
 \beta_m &= \frac{\delta \text{E}\left(\bar{W} \mid \bar{z}_{pm}\right)}{\delta \bar{z}_{pm}} \bar{W}^{-1} \\
 \gamma_{m,n} &= \frac{\delta^2 \text{E}\left(\bar{W} \mid \bar{z}_{pm}\right)}{\delta \bar{z}_{pm} \delta \bar{z}_{pn}} \bar{W}^{-1}
 \end{aligned} \tag{3}$$

356 where  $m$  and  $n$  index the  $m$ th and  $n$ th elements of the RN parameter vector  $\mathbf{z}_{\mathbf{p}}$ . Morrissey and Sakrejda  
 357 (2013) 's method elegantly unifies LMM and GLMM approaches to estimating selection on latent behavioral  
 358 RNs.

### 359 3.1.5 Within-generation effects of selection

360 With appropriate linear and nonlinear selection gradients, the expected within-generation effect of selection on  
 361 the population means and covariances of behavioral RNs can be estimated. In particular, selection differentials  
 362 can be calculated that integrate direct adaptive effects due to  $\boldsymbol{\beta}$  and  $\boldsymbol{\gamma}$  with indirect effects caused by trait  
 363 integration due to  $\mathbf{P} = \mathbf{SRS}$ . Following Lande and Arnold (1983), linear and quadratic differentials are  
 364 defined such that

$$\begin{aligned}
 \Delta_{\text{T}} \bar{\mathbf{z}}_{\mathbf{p}} &= \mathbf{P} \boldsymbol{\beta}, \\
 \Delta_{\text{T}} \mathbf{P} &= \mathbf{P} \left( \boldsymbol{\gamma} - \boldsymbol{\beta} \boldsymbol{\beta}' \right) \mathbf{P}
 \end{aligned} \tag{4.1}$$

365 where  $\Delta_{\text{T}}$  indicates the total (i.e. direct and indirect) within-generation effect of selection. We can also  
 366 consider the effects of selection in the hypothetical case of complete independence between RN parameters by  
 367 instead using a diagonal matrix  $\mathbf{V} = \mathbf{S}^2$  of trait variances.

$$\begin{aligned}
 \Delta_{\text{D}} \bar{\mathbf{z}}_{\mathbf{p}} &= \mathbf{V} \boldsymbol{\beta}, \\
 \Delta_{\text{D}} \mathbf{V} &= \mathbf{V} \left( \boldsymbol{\gamma} - \boldsymbol{\beta} \boldsymbol{\beta}' \right) \mathbf{V}
 \end{aligned} \tag{4.2}$$

368 Here,  $\Delta_{\text{D}}$  indicates change expected under trait independence, thus isolating the direct effects of selection on  
 369 adaptation. Visual and quantitative comparison of the expected patterns of change between the integrated

total  $\Delta_T$  and independent direct  $\Delta_D$  differentials provides a useful and straightforward means of estimating the degree to which phenotypic integration constrains or facilitates the adaptive process through indirect effects (Conner 2012). Moreover, separation of these differentials allows for straightforward testing of adaptive hypotheses on specific behavioral parameters, even in the presence of high-dimensional data, strong phenotypic constraints, and highly nonlinear selection surfaces. If  $\Delta_D \bar{z}_{pm} > 0$  for RN parameter  $m$ , then selection is acting to increase the mean trait value in the population (and vice versa for negative change). Similarly,  $\Delta_D \mathbf{V}_{m,m} > 0$  indicates that selection is acting to increase individual variation in the population, such that individuality is likely to be adaptive, while  $\Delta_D \mathbf{V}_{m,m} < 0$  indicates that individuality is being selected against. For the off-diagonal elements,  $\Delta_D \mathbf{V}_{m,n} \neq 0$  indicates that selection is actively promoting positive or negative trait integration between RN parameters  $m$  and  $n$ , suggesting that behavioral syndromes are also adaptive. As shown in **Figure 3**, it will often be helpful to express these covariances as correlations for ease of comparison and visualization.

### 3.1.6 Visualizing the effects of multivariate selection

When modelling selection on a single RN parameter, it is straightforward to relate concave or convex quadratic gradients in Eq 1.2 or Eq 2 to the shape of the the fitness function, which is standard in presentations of stabilizing and disruptive selection surfaces. With two RN parameters, a response surface methodology can be used to visualize a variety of more complex surfaces characterized by domes, bowls, and saddles, among other 3-dimensional shapes. These scenarios are shown in **Figure 2**. Things become more complicated, however, when three or more parameters experience correlational selection. In such cases, some evolutionary biologists have argued for the use of single value decomposition methods such as canonical analysis to enhance interpretation of the selection process (Blows 2007; Phillips and Arnold 1989). With this approach, the fitness model can be re-expressed on the primary axes of correlational selection, facilitating more intuitive visualization of linear and quadratic selection on conditionally independent dimensions. While undoubtedly useful in particular empirical contexts, this method has many limitations for general application that have inhibited its uptake among empiricists, including sensitivity to sampling error and units of measurement (Morrissey 2014), as well as the general difficulty of interpreting the meaning of traits defined by their statistical rather than biological properties (Brodie and McGlothlin 2007; Conner 2007). While the dimension reduction capacities of this approach are highly desirable when considering selection on multi-trait RNs, more theoretically motivated approaches such as structural equation or generalized network modelling can instead be applied to categorize latent behavioral characters governing multiple RN parameters (Araya-Ajoy and Dingemans 2014; Martin et al. 2019). In contrast to these causal modelling approaches, which seek to disentangle evolutionarily meaningful patterns of common and unique variance due to latent factors, methods such as canonical analysis are principally data reduction techniques and thus categorize axes irrespective of whether they confound common and unique sources of variation in fitness effects. This is why uncertainty in particular traits is expected to easily bias the axes characterized by canonical analysis (Morrissey 2014), while structural equation models are robust to trait measurement error (Bollen and Noble 2011). When causal modelling techniques are not well-motivated for a multi-trait RN, strong regularization techniques can instead be employed to enhance inferences and reduce the effective parameter space. This can be accomplished with the proposed models by implementing priors such as the regularized horseshoe prior (Piiroinen and Vehtari 2017), which performs well under conditions where the number of parameters is greater than would otherwise be desirable for the sample size.

Canonical analysis is, therefore, not considered further as a means of effectively visualizing multivariate selection, though the provided model code can always be modified to carry it out nonetheless. Non-parametric methods are also not considered herein as an alternative. While such methods are useful for hypothesis generation, it is ultimately parametric functions (perhaps of a highly complex nonlinear structure) that will facilitate robust theories of adaptation amenable to formalization and comparative biological research on individual variation. Non-parametric techniques such as projection-pursuit regression (Morrissey 2014; Schluter and Nychka 1994) should thus be considered useful and complimentary tools for the proposed parametric models, which can be always be elaborated upon to capture the essential features of any function generated through exploratory non-parametric analysis. Indeed, one can always extend a parametric GLMM to a generalized additive multilevel model (Pedersen et al. 2019) by including additional non-parametric functions such as splines and Gaussian processes into a selection analysis, facilitating biological comparison and straightforward hypothesis testing while also capturing any unmodelled sources of nonlinear association that may bias parametric inferences. This can be accomplished within a Bayesian framework in Stan using methods implemented in the “brms” R package (Bürkner 2017).

425 Given these considerations, how can we effectively visualize the effects of multivariate, nonlinear selection on  
 426 behavioral RNs? I propose a simple method that considers how selection influences behavioral RNs in three  
 427 dimensions. The motivation for this method begins by considering the unique pieces of information provided  
 428 by the selection differentials in Eq 4.1 and Eq 4.2. Firstly,  $\Delta\mathbf{z}_p$  inform the expected change in the mean  
 429 of each RN parameter, while the diagonal elements of  $\Delta\mathbf{P}$  informs the change in the variance of each RN  
 430 parameter. The off-diagonal elements of  $\Delta\mathbf{P}$  instead capture changes in the integration among RN parameters,  
 431 which can be standardized to correlations for ease of interpretation. The effect of direct versus indirect  
 432 selection effects caused by RN parameter integration can be further informed by the difference between  $\Delta_D$   
 433 and  $\Delta_T$  respectively. This allows researchers to assess adaptive hypotheses on specific trait values even when  
 434 phenotypic integration is expected to diminish or even reverse the direction of evolutionary change caused  
 435 by direct selection. Finally, because each element of  $\mathbf{z}_p$  is a parameter in a broader parametric behavioral  
 436 RN function, we can also consider each of these estimates together to indicate how selection is changing the  
 437 overall shape of the population behavioral strategy. Each of these pieces of information is to some degree  
 438 unique and informative for our theoretical understanding of adaptive individual variation. Therefore, the  
 439 proposed method is simply to plot all of this information together in a single figure of multivariate selection  
 440 effects on the behavioral RN, along with the posterior uncertainty in the expected effects of selection. This  
 441 visualization method is demonstrated in **Figure 3** for a hypothetical empirical scenario characterized by  
 442 directional, quadratic, and correlational selection on personality, plasticity, and predictability. Note that all  
 443 of these estimates are taken on the latent linear scale defined in the model, but they can always be predicted  
 444 on the original data scale by applying the appropriate inverse link function on the transformed absolute  
 445 values (i.e. link-scale population RN value + expected population RN change).

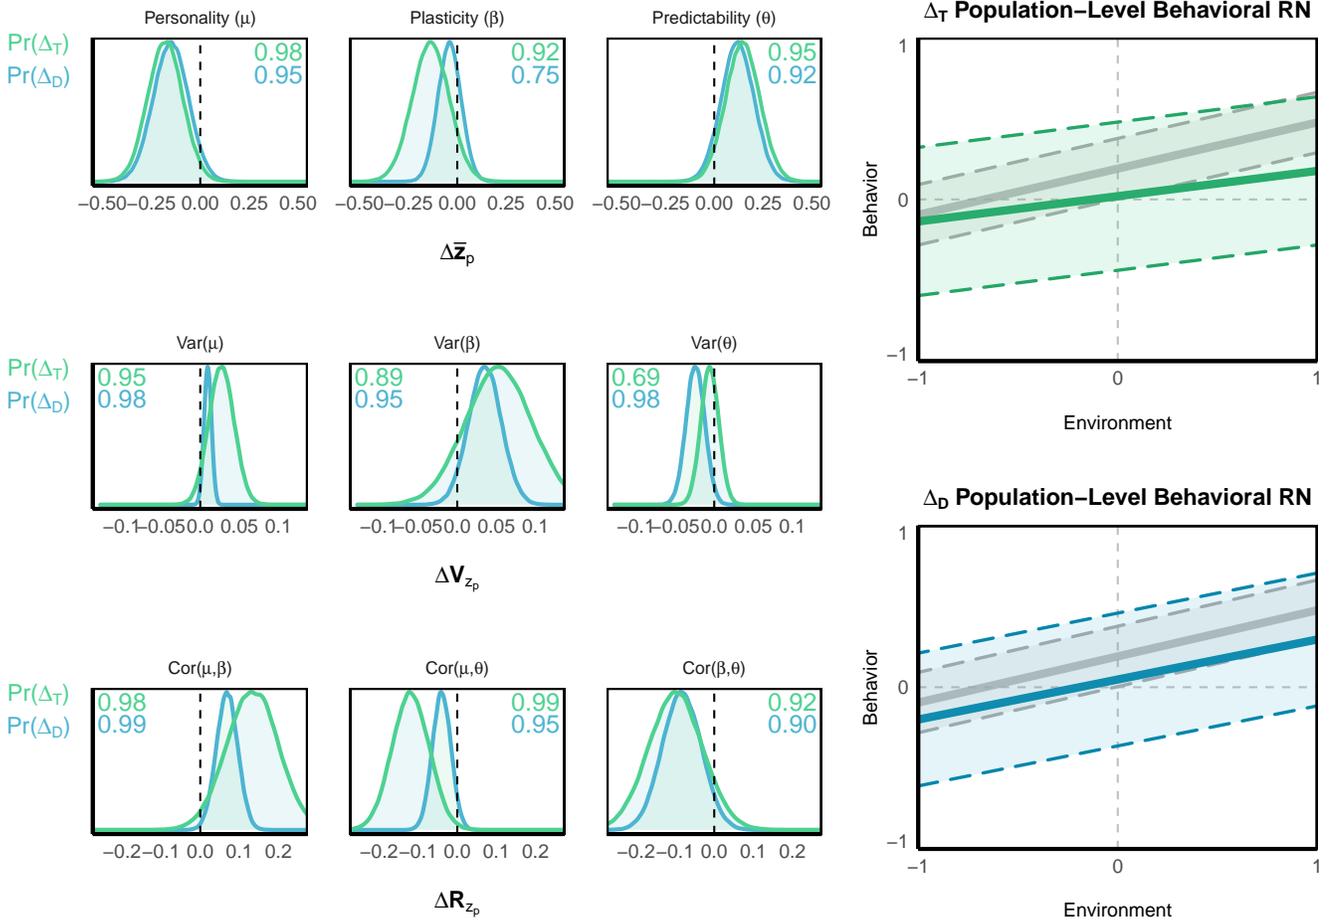

#### 446 4 Simulation-based calibration of proposed models

447 I used a simulation-based calibration (SBC) procedure to validate the inferential performance of the proposed  
 448 Bayesian models and assess whether they provide unbiased estimators of selection. SBC is a procedure for  
 449 validating the performance of any Bayesian algorithm across a broad range of possible parameter values, as  
 450 defined by the prior distributions of a generative model. This approach removes the arbitrariness of setting  
 451 a limited range of fixed parameter values for assessing performance, which can lead to unexpected sources  
 452 of bias being overlooked in uninvestigated regions of parameter space (e.g. rare but possible combinations  
 453 of RN correlations, standard deviations, and selection coefficients). Instead, random parameter values are  
 454 repeatedly imputed during each MCMC iteration of model estimation for a large number of simulations  
 455 and visual inspection of the correspondence between the generative distributions and subsequent posterior  
 456 distributions is used to detect any sources of bias, such as overdispersion in the estimator or inconsistent  
 457 performance for extreme values. While a detailed explanation of SBC implementation and interpretation  
 458 is beyond the scope of the present study (see Talts et al. 2018 for further details), it suffices to say that  
 459 a GLMM validated through SBC is an unbiased Bayesian estimator. This method was, therefore, used to  
 460 ensure that empirical studies using the proposed models would be expected to arrive at unbiased estimates  
 461 over a plausible range of possible parameter values.

462 Particular attention was given to the estimation of linear and nonlinear selection coefficients during SBC,  
 463 using 250 simulated datasets with 400 independent posterior samples each, resulting in the exploration of  
 464 100,000 random samples of all model parameters. As recommended by Talts et al. (2018), visual inspection  
 465 of the SBC diagnostic plots demonstrated that the ranks of posterior selection coefficients were consistent  
 466 with a random, uniform distribution around the prior simulated values, suggesting desirable performance  
 467 indicative of unbiased inference. Following the recommendation of Cook, Gelman, and Rubin (2006), I also  
 468 further tested the uniformity of the rank distribution by sorting ranks into eight evenly distributed bins  
 469 and applying a simple null-hypothesis test,  $\chi^2(7) = 6.06, P = 0.53$ , further suggesting that coefficient ranks  
 470 were randomly and evenly distributed. In other words, posterior inferences were not systematically upwardly  
 471 or downwardly biased from the true values, indicating that the proposed models are expected to provide  
 472 unbiased estimators of selection on behavioral RNs across a broad range of parameter space.

#### 473 5 Conclusion

474 Understanding the adaptive evolution of individual variation is an exciting and bustling frontier in evolutionary  
 475 ecology. Repeatable individual differences in behavioral consistency, plasticity, and predictability have now  
 476 been demonstrated across a broad range of taxa under a variety of ecological conditions. The challenge for  
 477 behavioral ecologists is thus no longer to simply document and describe between-individual differences in

**Figure 3:** Proposed representation of multivariate selection on a behavioral RN. Plots are shown for the within-generation effects of a hypothetical selection event, where selection was characterized by a combination of directional, quadratic, and correlational fitness effects across RN parameters. Distinct outcomes are shown for the direct effects of selection ( $\Delta_D$ ) causing adaptation independent of trait covariation, as well as the total effects of selection ( $\Delta_T$ ) accounting for indirect effects due to phenotypic integration among RN parameters.

**Left panel:** Three rows are shown for the distinct effects of multivariate selection on the average population RN parameter values ( $\Delta\bar{z}_p$ ), individual variation in population RN values (represented by the population variance,  $\Delta\mathbf{V}_{z_p}$ ), and the integration among RN parameters (represented by the population correlations,  $\Delta\mathbf{R}_{z_p}$ ). Uncertainty around these predicted changes is captured by posterior distributions of each selection differential, with the posterior probability  $\Pr(\Delta)$  supporting the expected direction of change for total and direct effects indicated in the top corner of each plot. If individual differences are adaptive, it is expected that selection will act to directly increase or maintain the population variance of RN parameters ( $\Delta_D\mathbf{V}_{z_p} \geq 0$ ); similarly, if positive trait integration is adaptive, selection will directly increase or maintain trait correlations (i.e.  $\Delta_D\mathbf{R}_{z_p} \geq 0$ ). Adaptation may nevertheless be constrained or accelerated by indirect effects due to phenotypic integration. In this hypothetical scenario, it can be seen that although selection is acting to decrease individual variation in predictability,  $\Pr(\Delta_D = 0.98)$ , indirect effects lead to no clear expected change in the population variance,  $\Pr(\Delta_T = 0.69)$ . Similarly, while there is only weak evidence of direct selection to decrease the mean plasticity in the population,  $\Pr(\Delta_D = 0.75)$ , indirect effects are expected to cause a more pronounced change,  $\Pr(\Delta_D = 0.92)$ .

**Right panel:** The expected change in the shape of the population behavioral RN following selection. The population RN prior to selection is indicated by the grey line and band. Point estimates from the posterior distributions of  $\Delta\bar{z}_p$  are used to visualize how direct and total selection effects shift the mean population RN across the relevant environmental gradient. The dashed, shaded bands indicate the 95% credible intervals (i.e.  $1.96 * \theta$ ) capturing the expected levels of behavioral predictability in the population.

478 behavior, but to instead test theory explaining how and why these patterns are observed (Dingemanse and  
 479 Wright 2020). It is now well-established that a variety of non-adaptive mechanisms can readily maintain  
 480 repeatable phenotypic variability and trait correlations within a population, particularly for traits with  
 481 complex genetic architectures. Therefore, the existence of such variation in itself does not provide strong reason  
 482 to suspect that natural selection is acting to increase or maintain individuality within a population. Bierbach,  
 483 Laskowski, and Wolf (2017), for example, found that personality emerged in activity level among clonal  
 484 fish raised in highly controlled environmental conditions, likely as a result of developmental noise. Similar  
 485 findings have been obtained for clonal mice, where individuality in behavior can result from subtle differences  
 486 in neurobiological and epigenetic responses toward standardized early rearing environments (Zocher et al.  
 487 2020). Processes such as mutation-selection balance also remain plausible explanations for the maintenance of  
 488 non-adaptive behavioral variation even in the presence of consistent stabilizing selection (Zhang and Hill 2005),  
 489 particularly for complex traits with large mutational target sizes caused by highly polygenic and pleiotropic  
 490 developmental pathways (Houle 1998; Boyle, Li, and Pritchard 2017). Empirical research in humans has, for  
 491 example, provided support for the role of mutation-selection balance in maintaining repeatable variation in  
 492 personality (Verweij et al. 2016), psychopathology (Keller 2008; Pardiñas et al. 2018), and general intelligence  
 493 (Hill et al. 2018). In light of these considerations, the mere existence of differential personality, plasticity,  
 494 and/or predictability within a population should not be considered biologically surprising, nor should it be  
 495 considered particularly informative on its own for advancing behavioral ecological theory (Beekman and  
 496 Jordan 2017). The onus thus remains on empiricists to demonstrate the evolutionary relevance of individual  
 497 variation within their study system, as well as to identify the common mechanisms and selection pressures  
 498 that may facilitate or diminish its maintenance across generations. While many such studies are now available  
 499 (e.g. Dingemanse and Réale 2005; Le Cœur et al. 2015; Le Galliard, Paquet, and Mugabo 2015), there is a  
 500 clear need for more phenotypic selection analyses on behavioral RNs in the wild. As John Maynard Smith  
 501 (1978) once noted, “The most direct way of testing a hypothesis about adaptation is to compare individuals  
 502 with different phenotypes, to see whether their fitnesses vary in the way predicted by the hypothesis” (p. 45).

503 A fundamental challenge for this research endeavor is to avoid inferential bias caused by using BLUP point  
 504 estimates of individuals’ latent personality, plasticity, and predictability parameters to predict fitness (Hadfield  
 505 et al. 2010), as these trait values are typically inferred with high degrees of uncertainty from GLMMs.  
 506 Previous attempts to address this issue (Houslay and Wilson 2017) have proposed using random effects  
 507 models to account for the uncertainty of BLUPs, but this approach restricts analyses to the estimation of  
 508 linear correlations and covariances among RNs and fitness. Ignoring non-linear associations fundamentally  
 509 inhibits researchers’ capacity to study adaptive individual differences, as persistent directional/linear selection  
 510 is expected to diminish rather than promote individuality within a population due to the exhaustion of  
 511 fitness-relevant additive genetic variance (Walsh and Blows 2009). To overcome this limitation, the present  
 512 study developed and investigated the properties of novel Bayesian models for studying nonlinear selection on  
 513 behavioral RNs. These models synthesize the Lande-Arnold selection framework (Lande and Arnold 1983)  
 514 with the GLMM framework for quantifying individual variation (Dingemanse and Dochtermann 2013) into a  
 515 single multi-response model, thus integrating uncertainty in BLUPs and their effects into a comprehensive  
 516 analysis. As a consequence, various complex forms of nonlinear selection—such as stabilizing, disruptive,  
 517 balancing, and/or correlational selection—can be estimated to test competing hypotheses of why variation  
 518 in RNs persists within a population. Given the challenge of visualizing high-dimensional selection surfaces  
 519 (Phillips and Arnold 1989), I further proposed a simple method for visualizing the expected direct and total  
 520 effects of selection on the evolution of behavioral RNs. This approach facilitates intuitive tests of adaptive  
 521 hypotheses on specific behavioral parameters, even in the presence of high-dimensional phenotypes and  
 522 complex selection surfaces.

523 It is important to note that selection differentials estimated from the proposed models (Eq 1.2 & Eq 2) will  
 524 be sensitive to missing fitness-relevant phenotypes or functional relationships, which is a deeper issue with  
 525 any trait-based model of selection and evolutionary change (Morrissey, Kruuk, and Wilson 2010). However,  
 526 behavioral ecologists are generally interested in developing and testing adaptive theory of selection, rather  
 527 than most accurately predicting patterns of microevolutionary change within a population. By focusing  
 528 on trait-based models, rather than pure variance-partitioning analyses, broader comparative patterns of  
 529 adaptation and selection can be better recognized and evaluated (e.g. Kingsolver et al. 2001). Nevertheless,  
 530 it is often useful to compare the predicted mean changes in phenotypic values between trait- and variance-  
 531 partitioning models, which can be used to assess the magnitude of effects that are being overlooked with the  
 532 fixed effects analysis (Morrissey et al. 2012). The random effect correlation models proposed by Houslay  
 533 and Wilson (2017) can thus provide complimentary analyses to the models presented here. As discussed  
 534 above, exploratory, non-parametric analyses can then be employed to detect and better characterize any  
 535 unspecified nonlinear functions on fitness, which can subsequently be integrated into the parametric model.

536 In this way, the goals of prediction and explanation, while distinct and in many cases best suited to different  
537 modelling approaches (Shmueli 2010), can nonetheless be integrated to better inform our understanding of  
538 microevolutionary change. The proposed modeling framework should, therefore, readily enhance tests of  
539 adaptive theory in the wild.
