Abstract

The R package *popharvest* was designed to help assess the sustainability of offtake in birds when only limited demographic information is available. In this article, we describe some basics of harvest theory and then discuss several considerations when using the different approaches in *popharvest* to assess whether observed harvests are unsustainable. Throughout, we emphasize the importance of distinguishing between the scientific and policy aspects of managing offtake. The principal product of *popharvest* is a sustainable harvest index (SHI), which can indicate whether harvest is unsustainable but not the converse. SHI is estimated based on a simple, scalar model of logistic population growth, whose parameters may be estimated using limited knowledge of demography. Uncertainty in demography leads to a distribution of SHI values and it is the purview of the decision maker to determine what amounts to an acceptable risk when failing to reject the null hypothesis of sustainability. The attitude toward risk, in turn, will likely depend on the decision maker's objective(s) in managing offtake. The management objective as specified in *popharvest* is a social construct, informed by biology, but ultimately it is an expression of social values that usually vary among stakeholders.

---

We therefore suggest that any standardization of criteria for management objectives in *popharvest* will necessarily be subjective and, thus, hard to defend in diverse decision-making situations. Because of its ease of use, diverse functionalities, and a minimal requirement of demographic information, we expect the use of *popharvest* to become widespread. Nonetheless, we suggest that while *popharvest* provides a useful platform for rapid assessments of sustainability, it cannot substitute for sufficient expertise and experience in harvest theory and management.

1 Introduction

Exploitation of birds by humans has a long history, with untold millions of birds taken worldwide for a variety of reasons, including for food, recreation, the pet trade, pest control, and as incidental take due to unrelated human activities (Shrubb 2013). In many, if not most, cases the demography of exploited populations and the impacts of offtake are poorly understood. To help address this challenge, the R package *popharvest* was designed to help assess the sustainability of offtake in birds when only limited demographic information is available (Eraud et al. 2021). Because of its ease of use, diverse functionalities, and a minimal requirement of demographic information, we expect the use of *popharvest* to become widespread. In this article, we discuss what we believe to be important considerations when using *popharvest*, particularly for an audience who may not be well-versed in harvest theory or management.

We emphasize that *popharvest* is simply a tool that makes methods developed by other authors more accessible. In particular, it builds on early work by Robinson and Redford (1991) and Slade et al. (1998) for large mammals. At about the same time, Wade (1998) developed what he called the Potential Biological Removal (PBR) method to determine acceptable levels of incidental take of marine mammals:

$$PBR = N_{min} \frac{R_{max}}{2} F_r$$

where N_{min} is a minimum population estimate, R_{max} (equivalently, r_{max}) is the maximum (i.e., intrinsic) rate of population growth, and F_R is a recovery factor between 0.1 and 1. The term $R_{max}/2$ is derived from the standard logistic model of population growth (i.e., assuming linear density dependence). It is the rate of offtake that maximizes the sustainable yield (MSY), while maintaining population size at half its carrying capacity. Thus, $F_r = 1$ seeks to maintain a population at its level of maximum net productivity ($K/2$). Niel and Lebreton (2005) used a variation of PBR, defining potential excess growth (PEG) as:

$$PEG = N\beta(\lambda_{max} - 1)$$

where N is population size, $(\lambda_{max} - 1) = R_{max}$, and β is a safety factor with 0.5 being a strict maximum. The PEG approach is implemented in *popharvest* with the safety factor β designated as F_s.

Runge et al. (2009) generalized the PBR approach to make it applicable to the full range of take scenarios and to better distinguish between scientific and policy elements of managing offtake. They called their approach Potential Take Level (PTL):

$$PTL_t = F_O \frac{r_{max}}{2} N_t$$

where $0 \le F_O \le 2$ is a factor that reflects management objectives; here $F_O = 1$ represents the goal of MSY. Like PBR and PEG approaches, PTL is based on the standard logistic population model, but unlike the former approaches emphasizes that potential levels of take are dependent on population size N_t that can change over time, *t*. All three approaches assume that carrying capacity and intrinsic growth rate are temporally constant. And, importantly, all three approaches assume that the population size is derived from a pre-breeding survey or census and includes both breeders and non-breeders. See Koneff et al. (2017) for a formulation of PTL that applies to post-breeding populations.

An extended version of the PTL approach developed by Johnson et al. (2012) is available in *popharvest*. This approach accounts for various functional forms of density dependence:

$$PTL_t = F_O \frac{r_{max}\theta}{(\theta + 1)} N_t$$

where $\theta > 0$ is the functional form of density dependence as either linear ($\theta = 1$), concave ($\theta > 1$), or convex ($\theta < 1$). It is this version of PTL that is available in *popharvest*, with F_O represented as F_{obj}.

The principal product of applications of *popharvest* is a sustainable harvest index (SHI), which is used to assess whether current harvest levels are unsustainable. SHI is calculated as the ratio of observed harvest to PEG or PTL, with values of SHI>1 indicating observed harvest is unsustainable relative to management objectives and/or risk tolerance. We emphasize, however, that the converse is not necessarily true. That is, values of SHI<1 are not conclusive of sustainability, analogous to a failure to reject the null hypothesis (i.e., harvest is sustainable). We are aware of only one published use of *popharvest*, in which Ellis and Cameron (2022) assessed the sustainability of waterbird harvests in the United Kingdom. However, there have been a number of applications that did not use *popharvest*, but did use PBR, PEG, or PTL approaches, including Watts et al. (2015), Runge and Sauer (2017), Koneff et al. (2017), Lormée et al. (2019), and Zimmerman et al. (2022).

In what follows we first describe some basics of harvest theory as background, and then discuss several considerations when using the different approaches in *popharvest* to assess whether observed harvests are unsustainable. Generally, these considerations fall into one of three categories: (1) ecology, (2) management objectives, and (3) uncertainty and risk. Most of these considerations are discussed in the article describing the *popharvest* package (Eraud et al. 2021), and our goal here is to simply emphasize and elaborate on them. Our motivation for doing so was derived from several experiences we have had in assisting others use *popharvest* (or its methods) and correctly interpret their results.

2 BASICS OF HARVEST THEORY

The harvest of wildlife is predicated on the notion of reproductive surplus, and ultimately on the theory of density-dependent population growth (Hilborn et al. 1995). This theory predicts a negative relationship between the rate of population growth and population density (i.e., number of individuals per unit of limiting resource) due to intraspecific competition for resources. In a relatively stable environment, un-harvested populations tend to settle around an equilibrium where births balance deaths. Populations respond to harvest losses by increasing reproductive output or through decreases in natural mortality because more resources are available per individual. Population size eventually settles around a new equilibrium and the harvest, if not too heavy, can be sustained without destroying the breeding stock. Managers of recreational harvest often attempt to maximize the sustainable harvest by driving population density to a level that maximizes the reproductive surplus (Beddington and May 1977).

One of the simplest and commonly used models to determine sustainable harvests for birds is the theta-logistic model:

$$N_{t+1} = N_t + N_t r_{max}\left[1 - \left(\frac{N_t}{K}\right)^{\theta}\right] - h_t N_t$$

where K is carrying capacity (i.e., the maximum number of animals the environment can support), h_t is harvest rate, and other terms are as described previously. The theta-logistic lacks age structure (i.e., a so-called scalar model) and so should be considered a first approximation if reproductive or survival rates are likely to be strongly age specific. The harvest rate *h* and harvest *H* for the maximum sustainable yield (MSY) are (Johnson et al. 2012):

$$h_{MSY} = r_{max}\frac{\theta}{(\theta + 1)}$$

$$H_{MSY} = r_{max}K\frac{\theta}{(\theta + 1)^{(\theta+1)/\theta}}$$

and the equilibrium population size *N* associated with MSY is:

$$N_{MSY} = K(\theta + 1)^{-1/\theta}$$

For the standard logistic with linear density dependence (i.e., $\theta = 1$), the management parameters simplify to:

$$h_{MSY} = \frac{r_{max}}{2}$$

$$H_{MSY} = \frac{r_{max} K}{4}$$

$$N_{MSY} = \frac{K}{2}$$

Thus, in the standard logistic model, the maximum reproductive (i.e., harvestable) surplus is attained at a population level of one-half carrying capacity. The sizes of the reproductive surpluses are parabolic with respect to population size (Fig. 1). We note that equilibrium population sizes are stable for harvests below MSY; i.e., harvests below MSY will always lead to an equilibrium population size greater than one-half carrying capacity, irrespective of stochastic fluctuations in population size or harvest. However, equilibrium population sizes are unstable if population size falls below one-half carrying capacity due to stochastic events and in that event even harvests < MSY can be unsustainable.

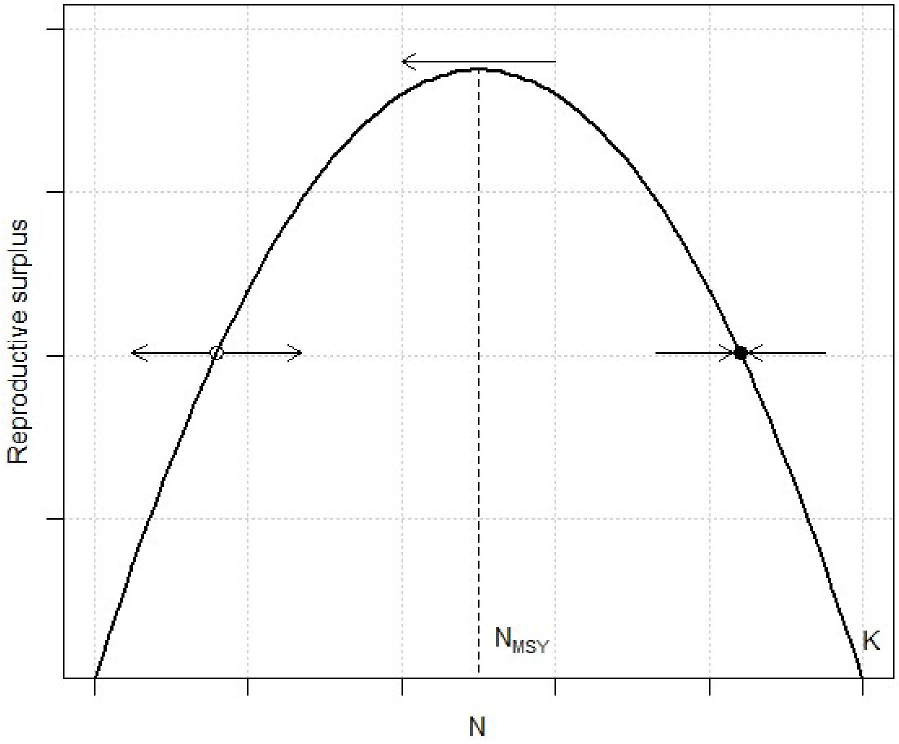

Fig. 1. Reproductive surpluses as a function of population size, N, from the standard logistic model (i.e., linear density dependence). Equilibrium population sizes to the right of N_{MSY} are stable (e.g., filled circle), while those to the left are unstable (e.g., open circle).

The scalar theta-logistic model underlies computations of PTL in *popharvest* and setting $F_{obj} = 1$ implies MSY. In the PEG approach, if one is willing to assume linear density dependence, MSY is implied by setting $F_s = 0.5$

3 ECOLOGICAL CONSIDERATIONS

For both the PEG and PTL approaches, it is necessary to have an estimate of $\lambda_{max} = (r_{max} + 1)$ or r_{max}, the intrinsic finite and net rates of annual population growth, respectively. That is:

$$N_{t+1} = N_t\lambda_{max} \text{ or } N_{t+1} = N_t + N_r r_{max}$$

These parameters will be unknown for most populations as they represent the rate of increase for populations under optimal conditions, absent any harvest or density-dependent effects. An advantage of *popharvest* is that it allows these rates to be estimated using only knowledge of maximum adult survival and age at first reproduction using the allometric relationships formulated by Niel and Lebreton (2005). Estimating the intrinsic adult survival may be as challenging as estimating r_{max}, however. An approach implemented in *popharvest* is to use the method of Johnson et al. (2012), who demonstrated how intrinsic adult survival could be estimated using body mass and age at first breeding by relying on complete survival histories of birds in captivity (which was thought to mimic optimal conditions).

When using the method of Johnson et al. (2012) to estimate intrinsic adult survival, bird mass must be specified as a fixed value or a lognormal distribution in *popharvest*, for example by using the compendium by Dunning (2008). But a question arises as to whether one should use the mass of males or females because sexual dimorphism will induce different values of r_{max}. Johnson et al. (2012) are silent on this question, but we suggest using both male and female body masses and calculating the mean mass as:

$$\mu = \frac{\mu_M + \mu_F}{2}$$

and its variance as:

$$\sigma^2 = \frac{\sigma_M^2 + \sigma_F^2}{2} + \frac{(\mu_M - \mu)^2 + (\mu_F - \mu)^2}{2}$$

Although we have no empirical support for this recommendation, it may be better than arbitrarily picking a single sex for the analysis.

Users of *popharvest* should be mindful, however, that the allometric approaches for estimating r_{max} are derived in an evolutionary context and, thus, it is a maximum that may not be attainable under contemporary ecological conditions. Moreover, one cannot rule out the possibility that r_{max} or carrying capacity are changing over time due to large-scale environmental forces such as climate change or ongoing habitat destruction. There is not likely anything one can do to account for this, other than to recognize that the use of r_{max} based on allometric relationships may overestimate a sustainable harvest level and therefore to manage risk accordingly.

In using the allometric approach of Niel and Lebreton (2005), one must decide if a species is “short-lived” or “long-lived,” and this can affect the magnitude of the estimate of r_{max}. Unfortunately, Niel and Lebreton (2005) don’t provide explicit guidance about how to make the distinction, although they only considered bird species that breed at age one year as “short-lived.” In any case, users of *popharvest* should be aware that designation of a species as “short-lived” will produce a higher value of r_{max} and, thus, suggest a higher level of sustainable harvest. For birds that breed at age one year, the difference in r_{max}. from the “short-lived” and “long-lived” approaches can be substantial. For birds that breed at age two years, the difference in the two approaches yield differences in r_{max} less than 0.1. The differences in the two approaches for birds that breed at ≥3 years are generally negligible (<0.05). In keeping with Niel and Lebreton (2005), we suggest the “short-lived” approach only be used for birds that breed at age one year.

We also note that survival estimates used to estimate r_{max} must be those attained under optimum ecological conditions (e.g., no density dependence and no harvest). Thus, empirical estimates of survival from the field may generate estimates of r_{max} (and sustainable harvests) that will be biased high. Finally, it’s also important to recognize that the default procedure in *popharvest* is to assume the survival of juveniles is less than adults only for the first year of life. If that is not the case, the user must supply a mean value for juvenile survival for birds between age one year and breeding age (α), but here one must assume that survival is constant for all birds aged 1 to α-1 years.

The PTL approach assumes that density dependence operates to reduce the realized growth rate as population size approaches carrying capacity. The approach relies on logistic growth of a scalar population and posits that populations can "compensate" to some extent for harvest by increasing reproduction and/or decreasing natural mortality. The compensation effect as incorporated in the logistic model is phenomenological, in the sense that no specific mechanisms are postulated (e.g., "compensatory" hunting mortality or heterogeneity in survival). The original PTL approach assumed linear density dependence ($\theta = 1$) (Runge et al. 2009), but Johnson et al. (2012) extended the approach to account for non-linear density dependence. In these cases, $\theta > 1$ produces a concave population response (when viewed from below), where density dependence is strongest nearest carrying capacity (Fig. 2). When $\theta < 1$, the population response is convex, where density dependence is strongest far away from carrying capacity. Users of *popharvest* should be aware that the functional form of density dependence (i.e., how growth rate declines as a function of increasing population size) can have a substantial effect on conclusions regarding sustainability. This can be problematic because the form of density dependence is typically the least understood and most difficult to estimate of all demographic parameters (Clark et al. 2010). In *popharvest* one can chose to estimate θ based on its apparent relationship with r_{max} (Johnson et al. 2012), but application of the method adds a great deal of uncertainty to conclusions regarding sustainability. It may be wise to examine both linear and nonlinear forms of density dependence to determine the sensitivity of SHI (Koneff et al. 2017). We end the ecological discussion of PTL by noting that while it explicitly recognizes a form of "compensation" to exploitation, other forms of population response are overlooked. For example, it does not account for potential "depensation" (or the so-called Allee effect; Stephens et al. 1999) where population growth rate can be low even when populations are far below carrying capacity (but see Haider et al. 2017). The Allee effect is most likely to manifest itself in severely depleted populations.

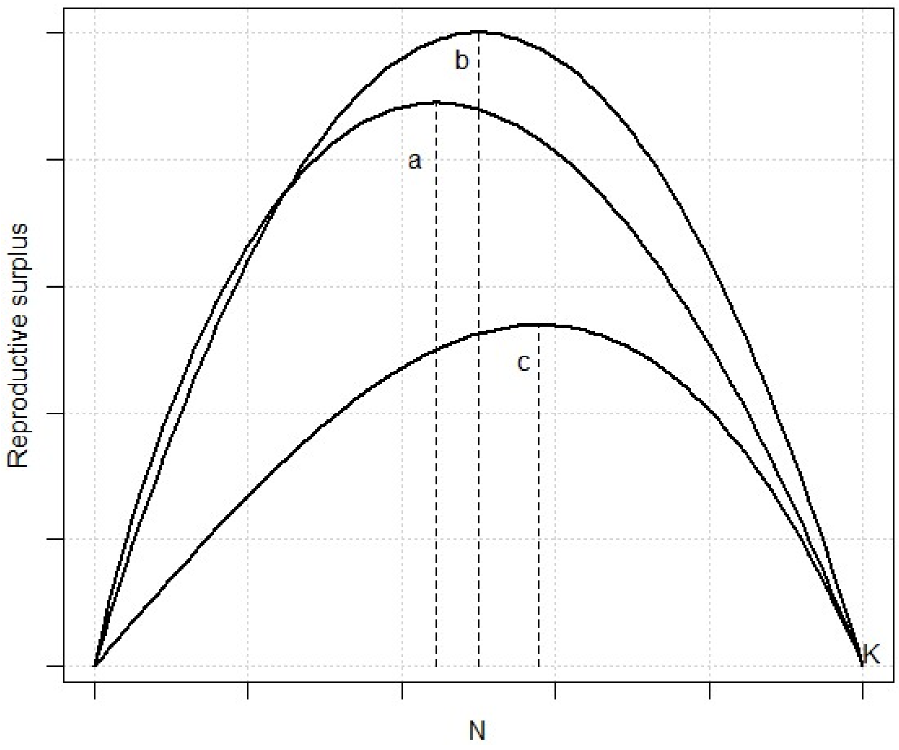

Fig. 2. Reproductive surpluses in the theta-logistic population model when density dependence is (a) convex ($\theta = 0.5, r_{max} = 1.5$), (b) linear ($\theta = 1.0, r_{max} = 1.0$), or (c) concave $\theta = 2, r_{max} = 0.35$. The vertical dashed lines indicate the equilibrium population sizes (N) for maximizing sustainable harvests.

There are several ecological considerations common to both PEG and PTL approaches. Both approaches rely on scalar models that do not account for any age structure in population demography nor in harvests. Significant age structure has important implications in terms of transient dynamics and population momentum (Koons et al. 2006). A failure to account for it can lead to spurious conclusions regarding the sustainability of harvest (Niel and Lebreton 2005, Hauser et al. 2006). Significant age structure is typically associated with longer-lived species. We note, however, that while geese are relatively long lived, there is at least one example demonstrating that scalar models may be adequate for assessing the consequences of harvest (Johnson et al. 2018).

Clearly defining a target population could help reduce the potential of unexpected consequences of applying PEG and PTL in local areas or for certain subpopulations. However, defining populations can be difficult due to course monitoring efforts or mixing of subpopulations when harvest occurs. Therefore, it is imperative that estimates of population size and harvest used to assess sustainability are both reliable and carefully aligned in time and space. This is especially critical in a European context because monitoring programs are extremely fragmented and sometimes produce biased estimates of population size or offtake (Elmberg et al. 2006, Aubry et al. 2020, Johnson and Koffijberg 2021) and because flyways and populations are not always well defined (Davidson and Stroud 2006). In North America, monitoring programs for game birds are quite advanced, but use of PTL and *popharvest* for permitting the take of non-game birds is increasing. In these cases, estimates of population size and offtake are tenuous at best. One must also be mindful that rapid assessments of sustainability are typically a “snapshot” in time and, thus, may not be reflective of sustainability over a longer period. Thus, we encourage users to estimate sustainable harvest for a range of population sizes. Finally, users of *popharvest* should be mindful that estimates of offtake must also include crippling loss, and this is problematic because crippling rates are only rarely monitored (Clausen et al. 2017). For ducks in North America, harvest estimates are often inflated by 20% to account for unretrieved harvests (Johnson et al. 1993). Ellis et al. (2022) reported a crippling rate of 22% for ducks in Illinois, USA.

4 MANAGEMENT OBJECTIVES

Perhaps the most challenging application of the methods used in *popharvest* involves specification of the safety factor F_S in PEG or the management objective F_{obj} in PTL. We cannot stress strongly enough that these F values are a social construct, informed by biology, but ultimately they are an expression of social values that usually vary among stakeholders. One of the difficulties users may have with the safety factor in PEG is that it confounds ecological understanding (e.g., presence of density dependence) and management objectives (e.g., risk tolerance) (Runge et al. 2009). Assessment of risk is the purview of decision makers and involves two components: (1) the probability of an undesirable outcome (e.g., unsustainable harvest) and (2) the perceived consequences (i.e., value) of that outcome. We may generally assume the conservationists are averse to risk, but the degree of risk aversion is a choice for decision makers and is likely to be heavily context dependent. Dillingham and Fletcher (2008) suggest using criteria from the International Union for the Conservation of Nature and Natural Resources (IUCN) to set $F_s = 0.5$ for 'least concern' species, $F_s = 0.3$ for 'near threatened', $F_s = 0.1$ for threatened species. However, these values are completely arbitrary and, more importantly, have not been sufficiently vetted among a large community of diverse decision makers. Moreover, categorization of species as, for example, "least concern," also involves somewhat arbitrary criteria. The IUCN criteria may exclude some specific life history information which could lead to spurious conclusions regarding sustainability. We therefore suggest that any standardization of criteria for F_s will necessarily be subjective and, thus, hard to defend in diverse decision-making situations. Close coordination with the decision maker(s) is thus essential in defining appropriate F values.

The PTL approach provides a better distinction between ecological understanding and management objectives (i.e., between the scientific and policy aspects of managing offtake). Rather than ask "is harvest unsustainable?" the PTL approach asks whether a given level of harvest is likely to meet management objectives for hunting opportunity and equilibrium population size. In the PTL approach, $0 < F_{obj} < (\theta + 1)/\theta$ where $F_{obj} = 1$ represents a desire to attain the maximum sustainable harvest (MSY). It is well known, however, that application of MSY in a variable environment is likely to be unsustainable (Ludwig 2001). To extract only a specified proportion p_{obj} of the MSY, one can specify as an objective:

$$p_{obj} = \frac{H < MSY}{MSY}$$

and solve for F_{obj} using:

$$p_{obj} = F_{obj}\left(1 + \theta\left(1 - F_{obj}\right)\right)^{1/\theta}$$

The associated equilibrium size of the harvested population as a portion of carrying capacity, K, is:

$$\frac{N}{K} = \left(1 - F_{obj}\frac{\theta}{(\theta+1)}\right)^{1/\theta}$$

As with F_s, we believe it would be difficult to standardize a protocol for specification of F_{obj} as it is the purview of the decision maker and likely to be context dependent. Specifying an acceptable F value for both the PEG and PTL approaches should always explicitly consider current and desired population sizes, intrinsic and observed population growth rates, the time required to meet management objectives, demographic uncertainty and risk tolerance, and possibly other considerations. Generally, however, $F_{obj} = 1$ might be considered for robust populations subject to recreational harvest, while $F_{obj} < 1$ might be appropriate for more vulnerable populations. Finally, $F_{obj} > 1$ might be appropriate for invasive populations or for those causing significant socio-economic conflicts.

5 UNCERTAINTY AND RISK

There are always uncertain demographic aspects in assessing harvest sustainability. Fortunately, *popharvest* provides tools to account for sources of uncertainty in estimates of intrinsic growth rate, population size, and harvest (e.g. Watts et al. 2015). We advise users of *popharvest* to take full advantage of these tools rather than specifying deterministic values, even if they are relatively well known. The admission of uncertainty in all aspects of applying *popharvest* will necessarily lead to relatively large uncertainty in the determination of sustainability, and any determination will likely be less conclusive than decision makers would prefer. However, explicit recognition of ecological uncertainty is essential to an honest and transparent appraisal of sustainability. Therefore, in confronting this uncertainty the decision maker must take responsibility for explicitly stating their risk tolerance.

To use *popharvest* to determine whether offtake may be unsustainable, we can define risk as the probability that a particular level of harvest exceeds the Sustainable Harvest Index (SHI), where values of SHI>1 are to be avoided. But what makes for an unacceptable probability

$P(SHI > 1)$? We can likely assume the decision maker will accept a lower probability (i.e. risk) if the population is small and/or declining rapidly. But, like other policy aspects of management decisions, an acceptable $P(SHI > 1)$ is the purview of the decision maker and will likely be context dependent.

One possible approach to standardizing the degree of risk acceptance is to rely on the concept of stochastic dominance (Levy 2016, Canessa et al. 2016). The idea is that the decision maker should be able to describe their subjective attitude toward risk as being risk averse, risk neutral, or risk seeking. If we generally believe conservation decision makers will be risk averse, then the decision maker would like to avoid both a large variance and negative skewness in the distribution of possible outcomes. To apply this concept using the output of *popharvest*, one would have to posit varying potential levels of harvest (including the observed harvest) and then compare the cumulative distribution functions of the stochastic outcomes of SHI for each. If, based on the concepts of stochastic dominance, the preferred choice of harvest is below that observed, a risk-averse decision maker could conclude that the observed harvest is inconsistent with the management objective F_{obj} specified in the PTL (for a risk-averse decision maker). Unfortunately, the ability to examine stochastic dominance does not exist in *popharvest* and would require ancillary programming. This feature may be included in subsequent updates of *popharvest*.

We offer a last brief comment about the fact that the PEG approach confounds ecological understanding and management objectives, or risk tolerance in this case. It has been suggested that the population size *N* used in the calculation of PEG should represent a minimum estimate to hedge against falsely concluding a harvest is sustainable (Wade 1998). Thus, it potentially passes a decision about risk attitude to the ecologist responsible for estimating population size. Overall, we prefer the PTL approach to PEG, bearing in mind the need to carefully distinguish between scientific and policy aspects of decision making.

6 CONCLUSIONS

We expect that the R package *popharvest* will encourage broader use of established methods for assessing the sustainability of offtake in birds, especially among conservationists and managers who may have limited expertise in harvest theory, decision analysis, and computer programming. However, its ease of use is also a disadvantage if the nuances of its application are not fully appreciated. In particular, we are concerned about the confounding of science and values that is all too common in conservation decision making (Pielke 2007). All conservation decisions involve both predicting and valuing outcomes. The first part is the (objective) role of scientists and the second part is the (subjective) role of society (or the decision maker as their representative). Thus, we urge caution in the use of the PEG method in which the distinction between these components is not as transparent as we believe it should be. The PTL approach, while better at separating ecological understanding and management objectives, nonetheless presents its own challenges in application. In particular, we believe it may be unrealistic to develop a standardized protocol for establishing F_{obj} values that are universally accepted within the ornithological community. An alternative for a rapid assessment of sustainability would be to set $F_{obj} = 1$ (i.e., MSY) and then flag those species with an unacceptably high $P(SHI \geq 1)$ as warranting a fuller consideration of relevant social values among the decision makers responsible for regulating the offtake of that species.

The presence of uncertainty in demographic parameters, extant population sizes, and harvest should be fully acknowledged in applications of *popharvest*. Where estimates of sampling variation are unavailable, the ecologist might seek expert opinion to help characterize the uncertainty (see e.g., Johnson et al. 2017). Here, as in other aspects of stock assessments, the expert elicitation procedure should be completely transparent and follow acceptable protocols (Morgan 2014, Hemming et al. 2018). Regardless of how it is specified, uncertainty in demography induces a distribution of SHI indices, which in turn characterize the risk of undesirable outcomes (i.e., a failure to meet management objectives). We may perhaps assume reliably that conservation decision makers are risk averse, but we should guard against risk aversion becoming an absolute expression of the precautionary principle, which elevates concern for a species status above all considerations. Indeed, if the precautionary principle were applied unthinkingly in harvest management, no level of harvest would be acceptable. Obviously, there is the need to carefully consider the risk attendant to a broader range of relevant social values (e.g., the potential for socio-economic conflict) when assessing a decision maker's risk tolerance.
