Abstract

The hyperdiverse plant family Asteraceae, with over 32,000 species globally, forms an iconic component of island floras, including many spectacular radiations, but a global picture of their insular diversity is lacking. Here, we uncover the global biogeographical and evolutionary patterns of Asteraceae on islands to reveal the magnitude and potential causes of their evolutionary success. We compile a global checklist of Asteraceae species native and endemic to islands and combine it with macroecological analyses and a phylogenetic review of island radiations. Asteraceae have a global distribution on islands, comprising approximately 6,000 native island species, with 58% endemics. Yet, diversity of the family on islands is lower than expected given its overall diversity. However, Asteraceae are the most diverse family on oceanic islands, suggesting an exceptional ability to thrive in isolation. In agreement with island biogeography predictions, native Asteraceae diversity increases with area and decreases with isolation, and endemism increases with both island area and isolation. The hotspots for insular diversity and endemism are Madagascar and the Caribbean, both being regions we identify as most lacking phylogenetic studies. We identify 39 confirmed island radiations, and 69 putative radiations that remain to be phylogenetically investigated, exceeding numbers for other iconic insular groups, such as birds. Our results reveal Asteraceae offer immense potential for research in ecology and evolution, due to their close tracking of island biogeography expectations, large sample sizes (species and radiations), cosmopolitan distribution, and high number of potentially undiscovered radiations.

22 Introduction

23 The top ten most diverse plant families make up 43% of Angiosperm species (Govaerts et al.,
24 2021). Understanding the distribution and drivers of diversity of these large families is thus a
25 crucial step towards explaining the success of flowering plants in general. Key biogeographical
26 settings for exploring the patterns and processes that shape angiosperm diversity are islands. Due
27 to their distinct boundaries, global distribution, and replication, island systems have played a cru-
28 cial role in the development of key evolutionary and ecological theories (MacArthur and Wilson,
29 1967; Losos and Ricklefs, 2010; Whittaker et al., 2008; Warren et al., 2015; Whittaker et al., 2017;
30 Gillespie et al., 2020). The geographic isolation and unique habitats found on islands have given
31 rise to remarkable angiosperm biodiversity that is often characterized by high levels of endemism
32 (Kier et al., 2009; Cai et al., 2023), adaptive radiations (Kim et al., 2008; Givnish et al., 2008),
33 paleoendemism (Fernández-Palacios et al., 2011; Veron et al., 2019), and repeated evolution of
34 convergent traits (Carlquist, 1965; Burns, 2019).

35
36 While islands are valuable natural laboratories for studying plant diversity, global-scale data
37 on the distribution of major plant families on islands are only starting to emerge. Recent global
38 studies have explored biodiversity patterns for a few major families and lineages on islands (Taylor
39 et al., 2021; Veron et al., 2021), factors impacting the assembly of island floras (Kreft et al., 2008;
40 Weigelt et al., 2015; Carvajal-Endara et al., 2017; König et al., 2021), and traits associated with
41 insular diversity (Grossenbacher et al., 2017; Nürk et al., 2019; Zizka et al., 2022; Barajas-Barbosa
42 et al., 2023). These studies reveal how links between island features (e.g., area, isolation, age),
43 functional traits (e.g. insular woodiness), and biogeographical rates are important determinants
44 of the number of native and endemic species of flowering plants on islands, whilst suggesting that
45 evolutionary success on islands may not necessarily mirror that found on continents (Fernández-
46 Palacios et al., 2021).

47
48 Out of all plant families, arguably the one most often associated with evolutionary success
49 on islands is the most diverse family of all - Asteraceae. Asteraceae (also known as the aster,
50 composite, daisy or sunflower family) boast the greatest species number of any plant family in the
51 world, with an estimated 32,000 - 34,000 species (“The Plant List (Version 1.1)”, 2013; Gostel and
52 Bonifacino, 2020; Govaerts et al., 2021). Species of this family occur on every continent except
53 Antarctica and are found in a wide range of habitats, but are most abundant in dry and semi-arid
54 habitats and in Mediterranean-type ecosystems, deserts, grasslands, and mountains (Funk et al.,
55 2009). Members of the family exhibit great variation in growth habit, from small annual herbs to
56 woody perennial shrubs, lianas, and trees, and even rarely epiphytic and aquatic plants.

57
58 On islands, Asteraceae are thought to be remarkably diverse, and often form an iconic compo-
59 nent of insular floras of both continental and oceanic origin. For instance, it is the most species-rich
60 family on the remote Juan Fernández Archipelago (Bernardello et al., 2006) with 30 native species
61 and 4 genera endemic to the islands, and is among the top five most diverse families on the large
62 continental island of Madagascar (Antonelli et al., 2022). Additionally, the family has high levels
63 of endemism on oceanic islands: a study by Lenzner et al., 2017 compiled diversity data on major
64 plant families across 14 oceanic archipelagos and found that Asteraceae had the highest number of
65 single-island endemics for the oceanic islands considered in the study. Their success in dispersal,
66 establishment, and diversification on islands has been suggested to result from a combination of
67 intrinsic factors (Carlquist, 1974; Crawford et al., 2009; Jeffrey, 2009): Asteraceae possess unique

68 fruit morphology that aids in long-distance dispersal (Carlquist, 1966; Heleno and Vargas, 2015);
69 the head-like inflorescence (capitulum) often attracts generalist pollinators; and many species are
70 capable of selfing (Grossenbacher et al., 2017).

71

72 In addition to a high native and endemic species richness on islands, Asteraceae are known for
73 their presumed propensity to radiate (that is, to undergo cladogenesis in-situ on islands at rela-
74 tively fast rates). Two recent studies reviewing adaptive radiations across flowering plants (Schenk,
75 2021) and adaptive radiations on oceanic islands across all taxonomic groups (Cerca et al., 2023),
76 both found Asteraceae to be overrepresented in terms of adaptive radiations compared to other
77 clades. Indeed, the family provides numerous examples of spectacular island radiations: *Scalesia*
78 on the Galápagos Islands (Fernández-Mazuecos et al., 2020), the woody *Sonchus* alliance on the
79 Canary Islands (Kim et al., 1996), *Dendroseris* on the Juan Fernandez Islands (Sang et al., 1994;
80 Cho et al., 2020). One of the textbook examples of adaptive radiation on islands is the Asteraceae
81 silversword alliance of Hawai'i, a clade of 33 species in 3 endemic genera (*Argyroxiphium*, *Dubau-*
82 *tia*, *Wilkesia*), which evolved from a common ancestor that colonized Hawai'i by a long-distance
83 dispersal event from North America around 5 million years ago (Mya), and which exhibit high
84 diversity in morphology and ecological adaptation (Baldwin and Sanderson, 1998; Carlquist et al.,
85 2003; Landis et al., 2018). Another notable example is the Hawaiian *Bidens*. The monophyletic 20
86 species of *Bidens* endemic to Hawai'i originated from a single colonization event c. 1.8 Mya, having
87 thereafter radiated across the archipelago, occupying a wide variety of different habitats including
88 sand dunes, lava fields, rainforests, and wetland bogs, and have the highest rates of speciation per
89 unit area documented for any island plant radiation to date (Knobe et al., 2012; Knobe, Bellinger,
90 et al., 2020).

91

92 An increasing number of phylogenetic studies focusing on selected island clades of Asteraceae
93 from specific islands or archipelagos (Strijk et al., 2012; Vitales et al., 2014; Landis et al., 2018;
94 White et al., 2020; Fernández-Mazuecos et al., 2020) are providing insight into the potential drivers
95 of diversification in those Asteraceae groups. One hypothesis is that the high diversity of Aster-
96 aceae on islands results from a combination of high continental diversity, high rates of long-distance
97 dispersal, and overall high rates of in-situ speciation that well exceed extinction rates (consistent
98 with the high net diversification rates observed in continental Asteraceae) (Katinas et al., 2013;
99 Mandel et al., 2019; Magallón and Castillo, 2009, Panero and Crozier, 2016).

100

101 While it is assumed from the above examples that Asteraceae are highly diverse on islands and
102 have a propensity to radiate, in fact, a complete global picture of the diversity and distribution of
103 the family is yet to be assembled. Furthermore, an assessment of Asteraceae's potential to radiate
104 across islands globally is still lacking, because previous studies focused solely on adaptive radia-
105 tions and/or on oceanic islands, and thus the magnitude of island radiations within the family is
106 unknown.

107

108 To address these issues, we compiled a global checklist of island Asteraceae and used this to
109 answer four key questions: 1) How does the island diversity of Asteraceae compare with that of
110 other families? 2) How is island Asteraceae diversity distributed across space and major clades
111 of the family? 3) What are the environmental and biogeographical drivers of native and endemic
112 insular diversity on islands? 4) How many island radiations have occurred within Asteraceae and
113 are there commonalities between radiations?

114

115 **Methods**

116 **Data collection**

117 **Island Asteraceae checklist**

118 We compiled a global checklist of Asteraceae native and endemic to islands. The foundation of the
119 island Asteraceae checklist was the Global Inventory of Floras and Traits (GIFT) database (version
120 3.0; Weigelt et al., 2020; Denelle et al., 2023). GIFT collates and leverages plant checklists and
121 floras with regional-level data on distribution, environment, and functional traits and has a partic-
122 ular strength in island floras. We started by extracting all Asteraceae checklists from GIFT where
123 there was at least one species native to an island. We did not consider islands with zero Asteraceae
124 in the database because many of these may be false negatives, since GIFT relies on published
125 floras disentangling the true absence of Asteraceae on an island from a data gap is challenging. To
126 facilitate comparison across regions and sources, the GIFT database records the original species
127 names and endemism status from the primary floras and checklists and standardizes the taxon-
128 omy against the World Checklist of Vascular Plants (WCVP, Govaerts et al., 2021). For the island
129 Asteraceae checklists we carried out additional curation. Because Asteraceae are a taxonomically
130 complex family, we matched WCVP standardized names against the Global Compositae Database
131 (GCD, <https://www.compositae.org/gcd>, Gostel and Bonifacino, 2020) and retrieved the name
132 status (accepted, uncertain, unaccepted) and the tribe and subfamily classification. We further
133 updated the GCD taxonomy to the latest classification outlined in Susanna et al., 2020 based on
134 the family-level phylogeny in Mandel et al., 2019.

135
136 The final dataset is a global checklist of Asteraceae native to islands and is composed of 915
137 island checklists (SD1) and supported by 240 primary sources (SD2). The global checklist of in-
138 sular Asteraceae is structured by island geographic units. For each island in the data set, we have
139 a checklist of Asteraceae species, name standardization (original name, WCVP name, and GCD
140 name status), reference to the primary source, intrafamily taxonomic classification, the floristic
141 status of the species (native, endemic, non-endemic) to that geographic unit, distribution, and
142 conservation status.

143

144 **Island features and environmental variables**

145 For each island in the global checklist, we gathered abiotic data on island features and climatic
146 variables known to be important predictors of global diversity on islands (MacArthur and Wilson,
147 1967; Whittaker et al., 2008; Kreft et al., 2008). Environmental data were available from GIFT,
148 which includes information on abiotic variables for each island in the data set. We extracted the
149 following variables: latitude and longitude, area (km²), distance to nearest mainland (distance,
150 km), surrounding landmass proportion (SLMP, sum of the proportions of landmass within 100,
151 1,000, and 10,000 km buffer distances (Weigelt and Kreft, 2013)), Last Glacial Maximum mainland
152 connection (GMMC), Last Glacial Maximum area (LGM area), island age (Mya), mean and maxi-
153 mum elevation (m), terrain ruggedness index (TRI, m), botanical continent (level 1, defined by the
154 Biodiversity Information Standards, and biome (Ecoregions, Dinerstein et al., 2017)). We classified
155 islands into two physical types based on past connectivity to the mainland: "continental" islands,
156 those located on the continental shelf or continental fragments and previously connected to the
157 mainland, and "oceanic" islands, built mainly by volcanic activity or sea-floor uplift or atolls and
158 never connected to another landmass. This classification was initially based on the geology category

159 in GIFT, but we manually adapted and assessed it for each island/archipelago. We also included a
160 "mixed" category, for archipelagos composed of a mixture of continental and oceanic islands. We
161 aggregated islands into "archipelago grouping", a refined and cleaned archipelago assessment based
162 on the GIFT archipelago levels (arch_lvl_1, arch_lvl_2, arch_lvl_3) to capture shared biogeo-
163 graphic and geologic history. For example, all the islands in the Caribbean are grouped together
164 in GIFT under the archipelago classification of the West Indies (GIFT arch_lvl_1), and for this
165 study, we refined the West Indies archipelagos classification to include the Greater Antilles, Lesser
166 Antilles, and the Bahamas as separate archipelagos. All cases in which the archipelago grouping
167 differs from the one in GIFT are highlighted in the data. Additionally, we collected data on four
168 climatic variables (CHELSA 2.1 (Karger et al., 2017)) for each island: annual mean temperature
169 ($^{\circ}\text{C}$), mean annual precipitation (kg m^{-2}), temperature seasonality ($^{\circ}\text{C}/100$), and precipitation
170 seasonality (kg m^{-2}). As a result, our global island Asteraceae checklist includes Asteraceae diver-
171 sity data and associated island spatial and environmental data (SD1).

172

173 **Comparison of island diversity among flowering plant families**

174 To contextualize the insular diversity of Asteraceae, we compared it with other flowering plant fam-
175 ilies by gathering island diversity data for all angiosperm families that natively occur on islands
176 following a similar procedure. From GIFT, we extracted every island checklist with at least one
177 native angiosperm species. Then for each family, we calculated the total number of species native
178 to islands and the total number of species endemic to islands. We calculated insular diversity for
179 each family across both (a) all island types (continental, oceanic, and mixed) and (b) only oceanic
180 islands. This provided us with a global assessment of island diversity across flowering plant fam-
181 ilies, illustrating which families have the greatest diversity of native and endemic species on islands.

182

183 To determine whether island diversity was higher or lower than expected given the overall num-
184 ber of species within each family, we ran binomial tests and simulated island communities. For
185 each angiosperm family, we performed a binomial test to compare the proportion of island species
186 to the proportion of total species of that family to angiosperms globally. The binomial test was
187 conducted using the `binom.test()` function in R, where "x" represents the number of native island
188 species (i.e. number of successes), "n" represents the total number of angiosperm species native to
189 islands (i.e. number of trials), and "p" represents the proportion of the family to angiosperms glob-
190 ally (i.e. probability of success). The number of species within each family and the total number of
191 angiosperm species globally (333,799) were calculated with the World Checklist of Vascular Plants
192 (WCVP, Govaerts et al., 2021), and the number of island-native angiosperm species (99,659) and
193 oceanic-island native species (23,853) were calculated with GIFT. With the binomial test, the null
194 hypothesis is that the observed proportion of a family on islands is equal to its frequency globally
195 (p), and the alternative hypothesis is that the observed proportion on islands is not equal to this
196 global frequency.

197

198 Additionally, for visualization purposes, we ran simulations to estimate the null expectation
199 of island diversity and compare it to the observed diversity for the ten most diverse families on
200 both all island types and oceanic islands. For the top ten families, we created a global pool that
201 represents the total number of species in each family overall. We randomly sampled from the global
202 pool to create island communities with the same total number of species as the actual number of
203 native island species overall (10,000 iterations). This gives a null distribution of the island diversity

204 for each family given the overall diversity of the family. We then compared the observed island
205 diversity to the null distribution.

206

207 **Modeling the biogeographical drivers of island diversity**

208 We used generalized linear mixed models (GLMMs) to understand which island features and envi-
209 ronmental variables are linked to Asteraceae (1) native species richness (NSR) and (2) proportion
210 of single-island endemics (pSIE) across islands. Prior to modeling, we carried out a thorough explo-
211 ration of the data following a protocol described in Zuur et al., 2010. This included inspection and
212 checks for potential outliers, distribution of response variables, zero inflation, collinearity among re-
213 sponse variables, pair-wise relationships between response and predictor, and non-independence of
214 the response variable. Several predictor variables showed high collinearity, in particular, variables
215 found to be correlated to isolation (distance, SLMP, GMMC, LGM area, latitude) and topography
216 (mean elevation, maximum elevation, TRI). Hence, we dropped correlated variables to retain one
217 predictor for isolation (SLMP) and one for topography (maximum elevation). Because several
218 predictor variables were skewed, we log-transformed area, SLMP, maximum elevation, mean an-
219 nual precipitation, temperature seasonality, and precipitation seasonality. All continuous predictor
220 variables were centered and scaled. Additionally, we multiplied SLMP (surrounding landmass pro-
221 portion) by -1 to convert this variable to a more intuitive proxy for isolation; with this inverse
222 transformation of SLMP, a higher -SLMP refers to a more isolated island. We removed islands
223 smaller than 1 km² because diversity on these islets is influenced by different processes (i.e. the
224 small-island effect (Whitehead and Jones, 1969 Schrader et al., 2020)). The final data set included
225 510 islands, 272 oceanic and 238 continental islands (SD3).

226

227 We used AIC model selection to select the best model for (1) NSR and (2) pSIE from among
228 a range of candidate models (19 for NSR and 15 for pSIE) (Table S1). In line with the current
229 literature recommendations, we fit the NSR models with a negative binomial and pSIE models
230 with a beta-binomial error distribution (Stoklosa et al., 2022).

231

232 In our global model for NSR, we fit a negative-binomial GLMM to predict total native species
233 with area, isolation (-SLMP), island type (categorical with two levels: oceanic and continental),
234 max elevation, and temperature seasonality, with archipelago included as a random effect. In our
235 global model for pSIE, we fit a GLMM using a beta-binomial and native species richness used as
236 weights to predict the pSIE with area, isolation (-SLMP), island type (categorical with two levels:
237 oceanic and continental), max elevation, and mean annual temperature, with archipelago included
238 as a random effect. All models were fit using the glmmTMB package in R (Brooks et al., 2017).

239

240 Island age is an important variable in island biogeography, correlated to species richness (Whit-
241 taker et al., 2008); however, island age is challenging to accurately estimate (Rijsdijk et al., 2020;
242 Price and Clague, 2002), and we do not have full coverage of age estimates for all islands in our
243 dataset. Therefore, we ran a model for both NSR and the pSIE that includes island age as an
244 additional fixed effect for the subset of oceanic islands where an age estimate was available (221
245 islands). We followed the General Dynamic Model of island biogeography (Whittaker et al., 2008)
246 and included island age as Age+Age².

247

248 To validate the fitted models, we assessed for collinearity in predictors via variance inflation

249 factor (VIF) scores and checked the residuals with the DHARMA package (Hartig, 2022), which
250 simulates the standardized residuals from the fitted model and also checks for overdispersion and
251 zero inflation. DHARMA reports statistical evidence of non-uniformity in the QQ plot. The plots
252 themselves indicated that the effect size of these deviations from the expected distribution is small,
253 and the significance of the deviation may be caused by the large number of data points (see Figure
254 S1).

255

256 **Island radiations within Asteraceae**

257 We conducted a literature review of island radiations within Asteraceae to (1) synthesize our un-
258 derstanding of island radiations in Asteraceae, how many radiations there are and where they
259 occur, (2) identify common characteristics shared between radiations, and (3) highlight understud-
260 ied clades and regions that are promising for future research. Radiations are generally defined as
261 rapid increases in the diversity of a lineage (Linder, 2008). In the context of island biogeography,
262 a radiation is typically considered to be the differentiation of a significant number of species in a
263 short period of time through in-situ cladogenetic speciation (via lineage splitting) occurring within
264 an island region, from a single common ancestor that colonized an island or (meta-)archipelago.
265 Radiations are often categorized as adaptive or non-adaptive based on a series of criteria (e.g.
266 Schluter, 2000). In this study, we were interested in both types of radiations, as together they
267 represent the diversity of cladogenetic mechanisms in the family, and we, therefore, include both
268 types and record radiation type strictly as assessed by the primary publication.

269

270 In our literature search, we considered an island radiation to include three or more endemic
271 species that are geographically restricted to an island or archipelago(s), and which result from
272 a single colonization event and thus share a common ancestor. While our primary goal was to
273 synthesize knowledge on the diversity of phylogenetically confirmed insular radiations within the
274 family, we also wanted to highlight potential understudied radiations that are promising groups
275 for future research. To this end, our review included both confirmed and putative radiations.
276 Confirmed radiations were backed up by a well-sampled published phylogeny of the island taxa
277 and mainland relatives, which has confirmed the island endemics to form a clade resulting from
278 a single colonization event, that is, they are not the product of multiple colonisations from the
279 mainland (Igea et al., 2015; Papadopulos et al., 2011). Putative radiations were defined as having
280 at least three endemic species from a genus occurring on an island or archipelago but have not
281 yet been fully sampled in a phylogeny; this designation is based on taxonomy alone and indicates
282 the need for future phylogenetic research. By focusing on genera in our definition of radiation, we
283 run the risk of missing insular radiations that are composed of multiple genera (e.g., as is the case
284 for the confirmed Hawaiian silversword alliance radiation) when they originated by a single colo-
285 nization (i.e. single ancestry). For both confirmed and putative cases, radiating clades distributed
286 across multiple archipelagos were considered as one insular radiation. For example, the Polynesian
287 *Bidens*, which are distributed across the Hawaiian, Marquesas, Society Islands, and Austral Islands
288 all result from a single colonization of the Pacific islands and were considered a single insular ra-
289 diation (Knope, Funk, et al., 2020). While delimiting radiations to their widest island range could
290 conceal the subsequent inter-regional radiations (e.g. the 20 monophyletic *Bidens* on Hawai'i),
291 we included the archipelago and island distribution in our review to retain this information. For
292 summary and visibility purposes, we grouped radiations into wider regions composed of groups of
293 islands and archipelagos, which are defined in Table SD4.

294

295 To identify insular radiations, we took a two-fold approach. First, we carried out a literature
296 search in Google Scholar using the keywords (Asteraceae OR Compositae) AND Island AND Ra-
297 diation. Second, we searched through the Island Asteraceae Checklist and filtered out genera with
298 at least three endemic species on an island or archipelago. The checklist has a major advantage
299 in helping to identify unknown or understudied potential radiations that would otherwise not be
300 captured in the traditional literature search. With the list of candidate radiations, we manually
301 assessed each potential case. If the radiation met our above criteria for "confirmed" radiation,
302 we collected data on the geographic distribution, island type, taxonomy, number of species, type
303 of radiation (i.e. adaptive or non-adaptive; as assessed by the original publication), traits often
304 hypothesized to be associated with island radiations (breeding system, dispersal syndrome, ploidy
305 level, hybridization), crown age, phylogenetic work done on the clade, and references. Charac-
306 teristics and traits were collected at the radiation level. If species in a radiation had different
307 traits, the radiation was marked as multi-state; for example, the *Lipochaeta-Melanthera* radiation
308 on Hawai'i is made up of both diploids and polyploid, and so we listed the ploidy level of this
309 radiation as mixed. When we could not confirm the radiation through a well-sampled phylogeny,
310 but taxonomic evidence indicated the group of endemic species might be a radiation, we marked
311 the group as 'putative radiation' and collected data on the geographic distribution, island type,
312 taxonomy, potential number of species, and references.

313

314 Results and Discussion

315 Asteraceae is one of the most diverse families on islands

316 Asteraceae is the largest plant family in the world, with 33,994 currently accepted species globally
317 (Govaerts et al., 2021). Our comprehensive checklist of insular Asteraceae shows that this family
318 is also remarkably diverse on islands: we found 6,135 species of Asteraceae are native to islands, of
319 which 3,535 (58%) are endemic to islands globally. On oceanic islands specifically, we found 1,833
320 native Asteraceae species and 955 (52%) endemic species.

321

322 As Asteraceae species are generally perceived to be good dispersers and excellent island colo-
323 nizers (Carlquist, 1966; Carlquist, 1974), the proportion of island native and endemic species of
324 the total Asteraceae species pool would be expected to be higher in Asteraceae than in other large
325 families, and higher than expected by chance. Surprisingly, our comparison between the diversity of
326 angiosperm families on islands showed that Asteraceae are not the most species-rich family across
327 all islands (Figure 1; Table S2) and that they are underrepresented in terms of island species given
328 its overall diversity (Figure 1; Table S3). Orchidaceae and Rubiaceae have the highest number
329 of native island species with 11,118 and 6,188 species respectively. The high insular diversity of
330 Orchidaceae and Rubiaceae is found disproportionately on large, tropical continental islands and
331 archipelagos (including New Guinea, Borneo, and the Philippines), which are not particularly rich
332 in Asteraceae species. On oceanic islands, Asteraceae are the most diverse family for both native
333 and endemic species. Yet, despite high species richness compared to other families, Asteraceae are
334 also underrepresented on oceanic islands given their overall diversity (Figure 1B).

335

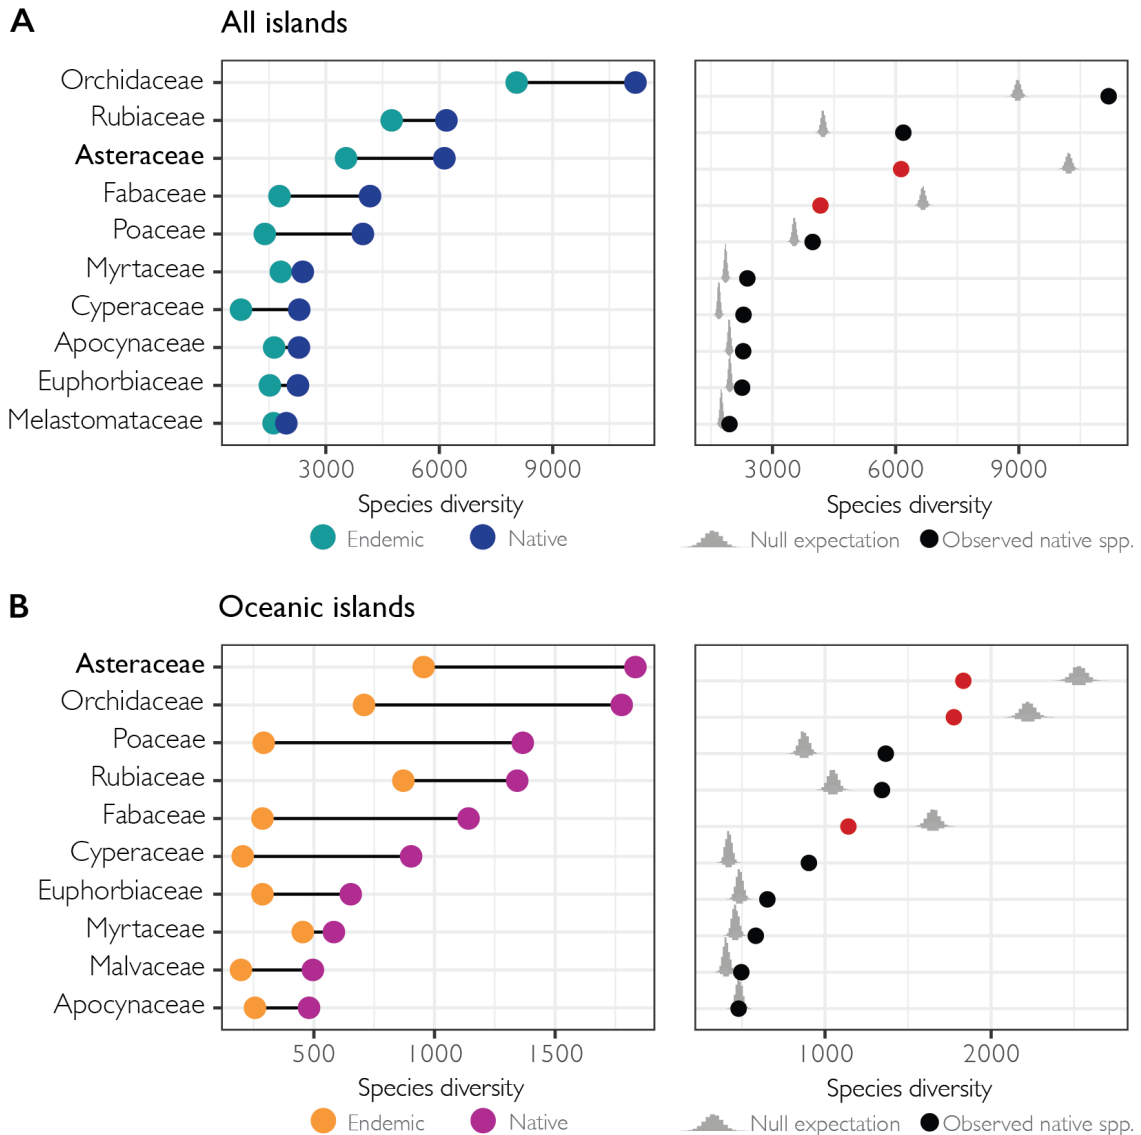

Figure 1: **The ten most diverse angiosperm families on (A) all islands and (B) oceanic islands, with the island diversity compared to the null expectation.** The left panel ranks the ten most diverse angiosperm families on all islands for native and endemic species. Families are ranked in descending order by the number of native species. The right panel compares the observed number of native island species per family (points) to the null expectation of island diversity (histogram). Families for which the observed number of species is lower than the null expectation are highlighted with a red point, and those above the null expectation in black. The global diversity of each family is listed in Table S2.

336 Island species account for 18% of the total species diversity of Asteraceae (Table S2). The
 337 results of the binomial test indicate that the observed number of Asteraceae species native to is-
 338 lands is significantly different than expected based on the proportion of Asteraceae to angiosperms
 339 globally (10%) and that the island proportion (6%) is significantly lower than expected under the
 340 null model (Table S3, Figure 1). Additionally, a comparison of the observed number of island
 341 Asteraceae species to the island community simulations confirms that the observed number of is-
 342 land species is lower than the null expectation across all islands and oceanic islands (Figure 1).
 343 While this result suggests Asteraceae may be poorer colonizers or have higher rates of extinction on
 344 islands relative to the mainland than previously expected, this can only be confirmed by estimating
 345 rates of colonization and diversification using species-level molecular phylogenies (Valente et al.,

346 2020), but given the enormous size of the family, this is yet to be realized.

347

348 **Asteraceae have a global distribution across islands**

349 Native species of Asteraceae have a truly global distribution across the world's islands (Figure 2).
350 In our global checklists, Asteraceae occur natively on 791 islands including 308 oceanic islands,
351 and across 146 archipelagos. Their distribution reaches north to the Svalbard Islands and Green-
352 land (80°N and 75°N) and south to Macquarie Island and Heard Island (55°S and 53°S). Insular
353 diversity ranged from 1 (minimum inclusion criterion) to 550 native species, with 29 islands (4%)
354 harboring more than 100 native species and 155 islands (20%) harboring only one native species
355 (our dataset only includes islands with at least one native Asteraceae species). Across all island
356 types, 128 islands (16%) have at least one endemic species.

357

358 While its distribution is global, the diversity of the family is not evenly distributed geographi-
359 cally, and several island regions are notable hotspots of diversity. Madagascar is the most diverse
360 island overall for both native (550) and endemic (487) species. The Caribbean, in particular the
361 Greater Antilles with 671 native and 430 endemic species, is another major center of island Aster-
362 aceae diversity. At the island level, the three large islands (Cuba, Hispaniola, Jamaica) are all in
363 the top ten most diverse islands globally for number of endemic species (196, 145, 58). This pat-
364 tern of the Caribbean as an important area of endemism for the family further supports a review
365 by Francisco-Ortega et al., 2008, who found that the region has the highest number of endemic
366 genera in Asteraceae globally. Across oceanic islands, Macaronesia, the Hawaiian Islands, and
367 the Mascarenes are hotspots of island diversity. The Canary Islands is the most diverse oceanic
368 archipelago with 299 native species, and 7 of the 10 most diverse oceanic islands for native species
369 are islands in the Canaries, with Tenerife being the most species-rich (159 species). The Hawaiian
370 Islands are the second most diverse oceanic archipelago with 102 native and 95 endemic species,
371 and have a remarkably high proportion of endemism (93%), followed by the Mascarenes with 79
372 native and 64 endemic species.

373

374 In comparing hotspot regions, the British Isles (850 native species, 368 endemic species) and
375 Iceland (334 native species, 261 endemic species) stand out as diversity anomalies. While these two
376 regions appear as hotspots of island diversity, the majority of species in these two island regions
377 are apomictic (Richards, 2003). Apomixis, a mode of asexual reproduction via seeds, is a poorly
378 understood trait in Asteraceae (Noyes, 2007) and one that challenges taxonomic species concepts
379 and delimitation (Haveman, 2013). To investigate the impact of apomictic species on our results,
380 we performed a sensitivity analysis with apomictic genera removed (see Figure S4), which revealed
381 minor changes to the ranking of top island hotspots, but no effect on our findings otherwise (in-
382 cluding the models).

383

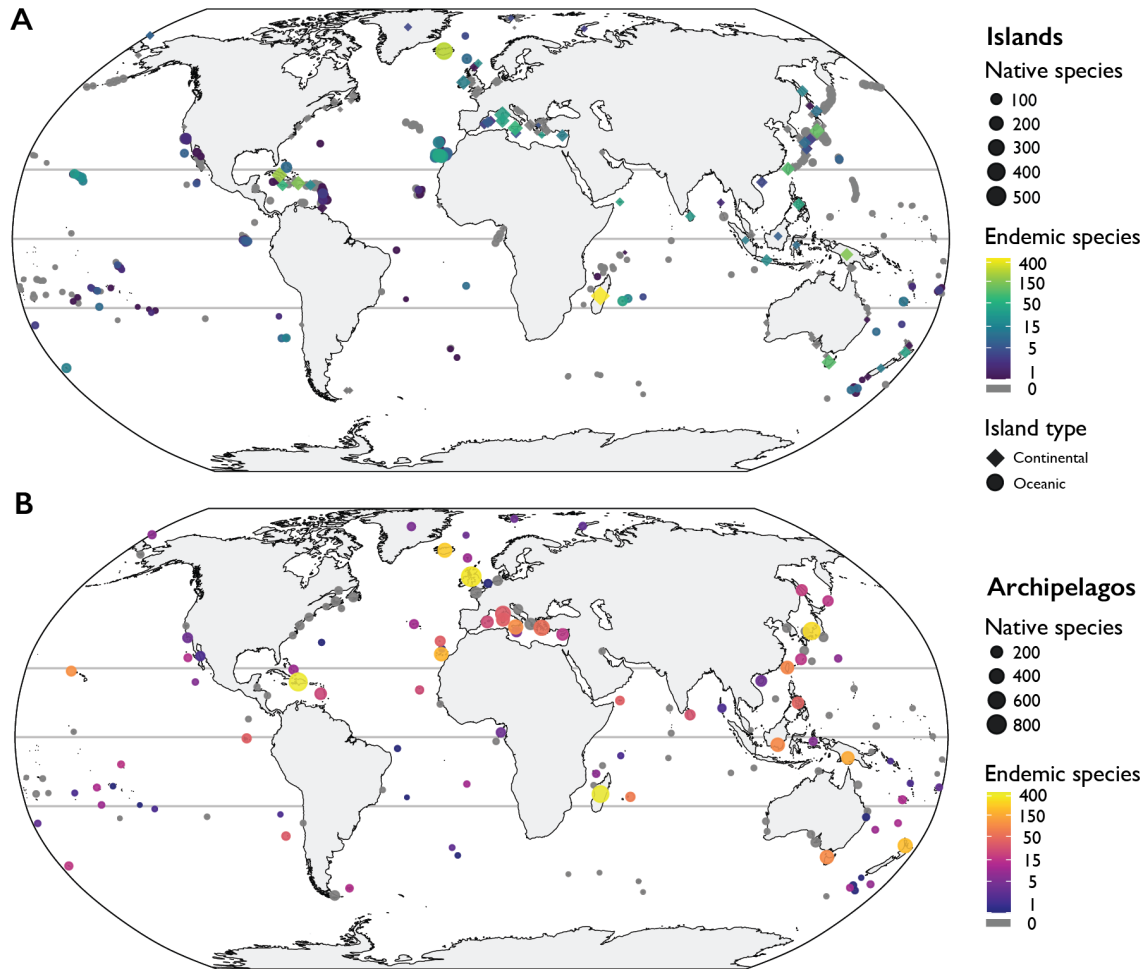

Figure 2: **Geographical diversity patterns of island Asteraceae.** (A) Global distribution of Asteraceae across all island types. The shape of the marker represents the island type (i.e. continental or oceanic), the size represents the number of species, and the color indicates the number of endemics, with grey meaning no island endemics. (B) Global distribution of Asteraceae on archipelagos.

384 The diversity of island species is also unevenly distributed across the major clades and taxo-
 385 nomic tribes of the family (Figure 3). The tribe with the highest number of native island species
 386 is Cichorieae (1660 spp.); while this tribe is an important component of island floras (e.g. *Tolpis*
 387 and the woody *Sonchus* alliance in Macaronesia, *Dendroseris* in the Juan Fernández Islands), its
 388 overall diversity is inflated due to the high number of apomictic species, well-known in this tribe
 389 (e.g. *Hieracium* on Iceland, *Taraxacum* on the British Isles). Aside from Cichorieae, the three most
 390 diverse tribes for both native and endemic island species are Astereae (793 native island species,
 391 465 endemic species), Senecioneae (653, 447), and Gnaphalieae (589, 339). Together, these four
 392 widespread tribes make up nearly 60% of all native insular Asteraceae species (Table S4, Fig-
 393 ure S2). While these tribes are also some of the largest tribes in the family, when we compare
 394 observed island diversity to expected diversity given the overall size of the tribe (Table S5), we
 395 find that island species are over-represented in Cichorieae, Astereae, and Gnaphalieae and within
 396 the expected range for Senecioneae. The two tribes with the highest proportion of native island
 397 species compared to the total diversity are Feddeae (100%) and Distephaneae (86%). Feddeae
 398 is a monotypic tribe with a single species, *Feddea cubensis* endemic to Cuba (Figure S2). The
 399 *Distephanus* clade is a group distributed across Africa, Madagascar, and the Mascarenes and has

400 a notable overrepresentation of island species relative to overall diversity (36 island species, 43
 401 total species) (Table S5). The intra-family diversity patterns are influenced by both the global
 402 distribution of a tribe and the presence of islands within that range. Asteraceae clades that have
 403 an overrepresentation of island species despite limited islands available within their overall range
 404 likely have intrinsic traits potentially well-adapted to islands.

405

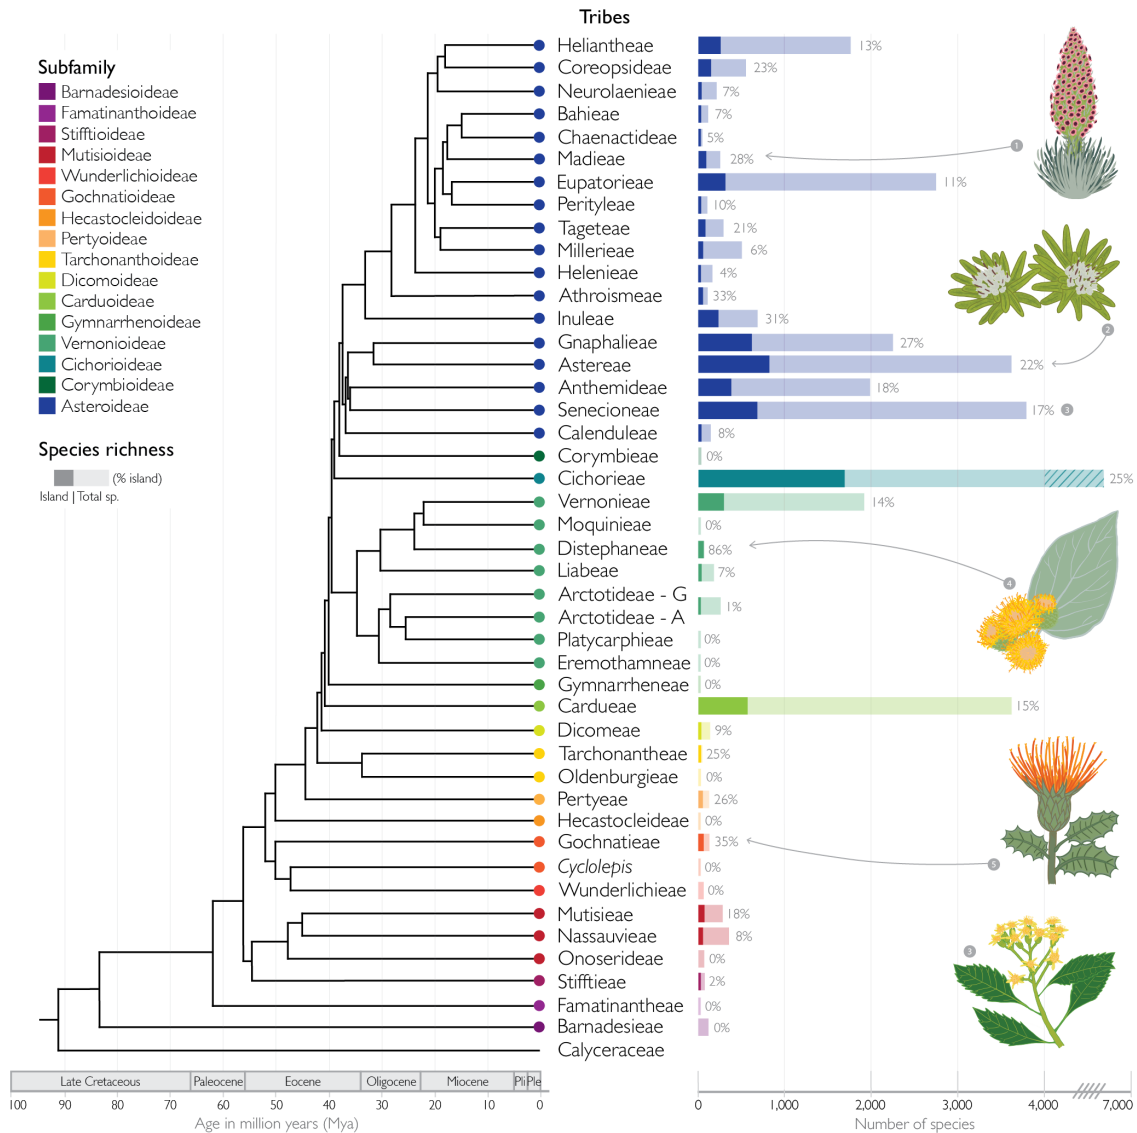

Figure 3: **Island diversity within the subfamilies and tribes of Asteraceae.** (A) Time-calibrated molecular phylogeny of the tribes and major clades within Asteraceae from Mandel et al., 2019. Tribes are colored by subfamily classification. (B) The number of species native to islands (dark bar) compared to the overall number of species globally (light bar) in each tribe. The percentage of native island species to total species globally is specified next to each tribe. Illustrations highlight clades with high island diversity: (1) *Argyroxiphium sandwicense* endemic to Hawai'i, Madieae; (2) *Abrotanella inconspicua* endemic to New Zealand, Astereae; (3) *Lordhowea insularis* endemic to Lord Howe Island, Senecioneae; (4) *Distephanus populifolius* endemic to Mauritius, Distephaneae; (5) *Anastrophia ilicifolia* endemic to Cuba, Gochnatieae. Illustrations by Lizzie Rooble.

406 Drivers of island species richness and proportion endemism

407 Species richness in Asteraceae follows classic island biogeography theory, with area and isolation
408 (-SLMP) being the strongest predictors of both NSR and pSIE (Figure 4). Area has a positive
409 association with NSR ($\beta = 0.64$, CI 0.56-0.72) and the pSIE ($\beta = 1.55$, CI 1.17-1.94) (Table S6).
410 This pattern of an increasing number of species with area conforms with both the species-area re-
411 lationship (Matthews et al., 2021) and the *Theory of Island Biogeography* (MacArthur and Wilson,
412 1967) and is well-supported across various island systems in other taxonomic groups (Kisel and
413 Barraclough, 2010; Triantis et al., 2012; Valente et al., 2020; Ohyama et al., 2021). While isolation
414 is a strong predictor of both NSR and pSIE, it has an inverse relationship on the two measures
415 of diversity, having a negative effect on NSR ($\beta = -0.32$, CI -0.45 - -0.19) but a positive effect on
416 pSIE ($\beta = 0.48$, CI 0.09-0.88), with more isolated islands having a higher proportion of endemism.
417 The increase in endemism with isolation is also a prediction of island biogeography, as MacArthur
418 and Wilson proposed the existence of a zone of radiation, where diversification should outpace the
419 dispersal-mediated build-up of species on near islands, and islands change from a dispersal- to an
420 evolution-driven system as isolation increases (MacArthur and Wilson, 1967; Losos and Schluter,
421 2000; Heaney, 2000; Valente et al., 2020).

422
423 Island type (oceanic vs continental), represents the geological origin of islands and is a proxy for
424 connectivity over time, affects both NSR and pSIE. Oceanic islands have fewer native species ($\beta =$
425 -0.38 , CI -0.57- -0.19), and a higher proportion of single-island endemics ($\beta = 1.36$, CI 0.48-2.23).
426 Maximum elevation has a positive effect on NSR ($\beta = 0.13$, CI 0.05-0.22), with higher islands hav-
427 ing more native species. Temperature seasonality is the best climatic predictor for NSR (positive
428 effect), and mean annual temperature is the best climatic predictor for pSIE (positive effect). In the
429 subset model that was filtered to oceanic islands and included Age+Age² as an additional predic-
430 tor, we did not observe an additional effect of island age on NSR nor pSIE (Table S7 and Figure S3).

431
432 Both the NSR and pSIE models have substantial predictive power in explaining island Aster-
433 aceae diversity (see methods and Figure S1 for model diagnostics). The overall variance (condi-
434 tional R^2) explained in the NSR model is 90% and the variance explained by the fixed effects
435 alone (marginal R^2) is 56% (Table S6) (Nakagawa R^2 (Nakagawa et al., 2017)). In a separate
436 model, with data aggregated for each archipelago, without random effects, the marginal R^2 was
437 75.1%, with model coefficients all pointing in the same direction as our original model (Table S8),
438 indicating the robustness of our qualitative results to geographical scale. In the pSIE model, the
439 overall variance (conditional R^2) explained by the model is 69% and the variance explained by the
440 fixed effects alone (marginal R^2) is 40%. Comparing the marginal and conditional R^2 , we find that
441 the inclusion of archipelago as a random factor contributes to a large proportion of the variance
442 explained in both the NSR and pSIE models. This is likely due to the nature of the island dataset
443 and the common biogeographic history of the islands belonging to an archipelago that contribute
444 to the conditional variance. There are 49 archipelagos in the dataset that are represented by a
445 single island - often due to limited floristic data available, and in these archipelagos, the mod-
446 els have high predictive power. Additionally, the main model patterns and relationships with the
447 predictors are unaffected when apomictic species are removed (see sensitivity analysis in Figure S4).

448

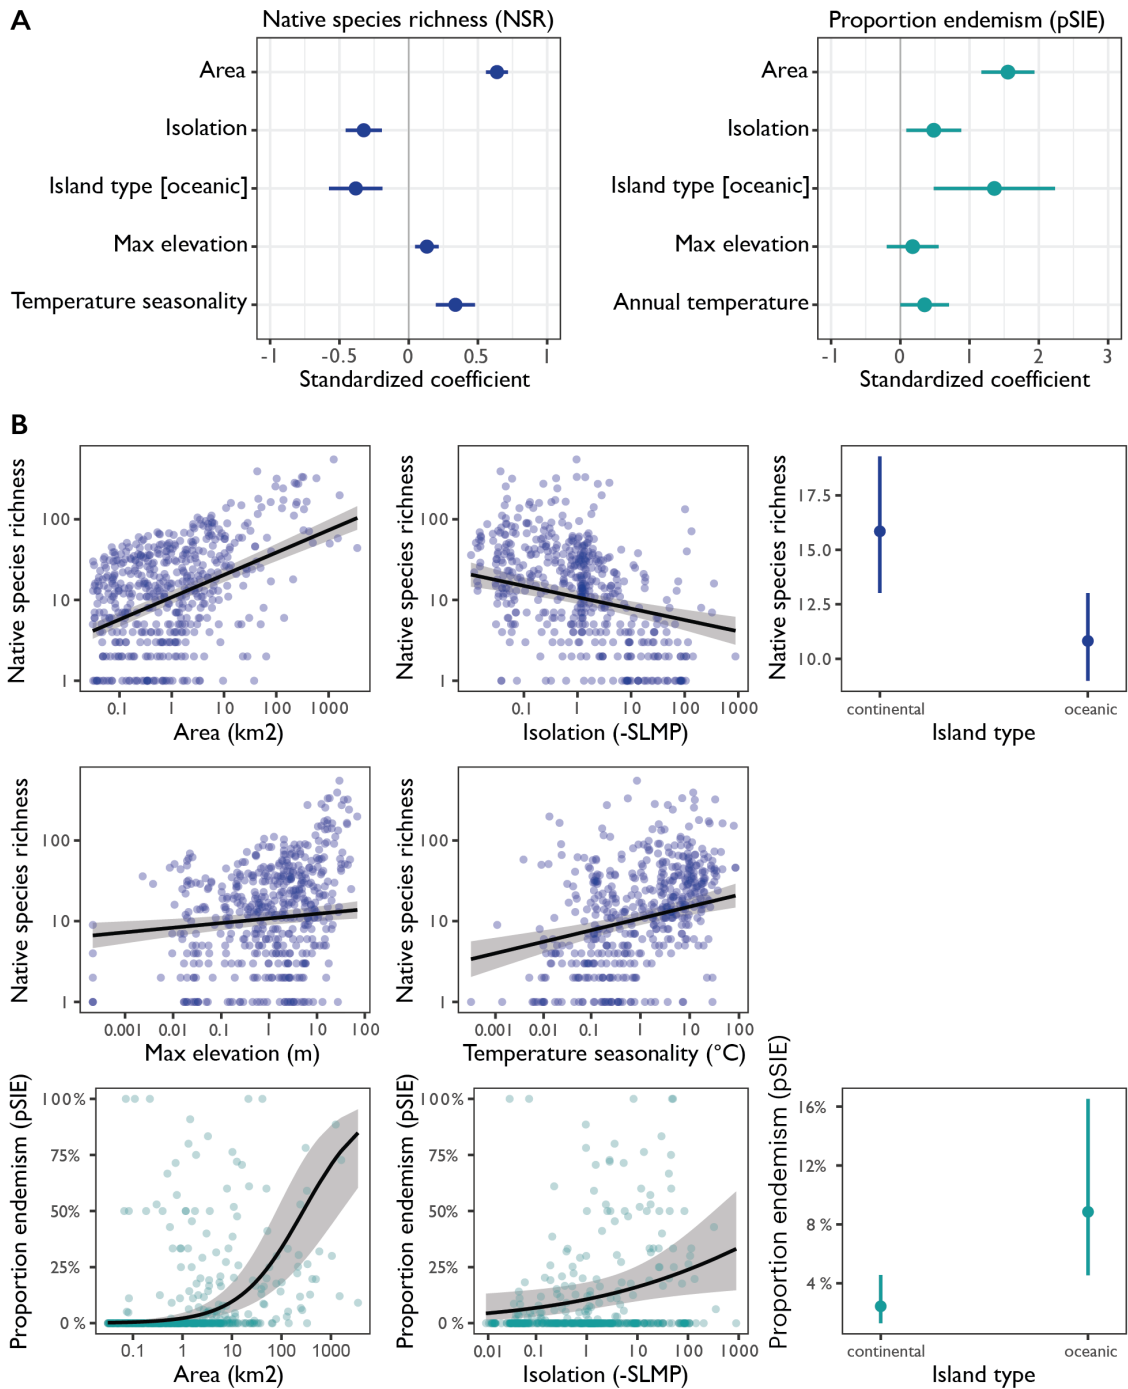

Figure 4: **The relative importance of island features and climatic variables on native species richness (NSR) and proportion of single-island endemics (pSIE).** (A) Coefficient estimates for the global models of native species richness (blue, top left) and the proportion of single-island endemics (green, top right). The bars around the coefficient estimates represent the standard error. The gray vertical line at 0 indicates no effect, and island variables with a positive coefficient estimate indicate an increase in NSR or pSIE, whereas a negative coefficient estimate indicates a decrease in the response variables. (B) Marginal effects for the significant island and environmental variables. The black line represents the predicted response under the model and the gray band is the 95% confidence interval. The following predictor variables were log-transformed: area, isolation (-SLMP), maximum elevation, and temperature seasonality.

449 **Island Asteraceae radiations have occurred nearly everywhere**

450 Apart from passerine birds of the Galápagos and Hawai'i, the *Anolis* lizards of the Caribbean, or
451 the lemurs of Madagascar, few groups of organisms evoke evolutionary diversification on islands
452 as much as Asteraceae, with its several "flagship" radiations - most famously the Hawaiian silver-
453 swords. However, to date, the geographical extent and number of insular radiations in the family
454 have only been studied for a subset of cases (exclusively adaptive radiations from a subset of oceanic
455 islands). We identified 39 phylogenetically-confirmed insular radiations and 69 putative radiations
456 across continental and oceanic islands, totaling 108 island radiations within the family worldwide.
457 The 39 confirmed radiations range in size from three (the minimum threshold) to 160 species, with
458 an average of 18 species per radiation (median = 11) (Figure 5, Table SD4). New Zealand and
459 surrounding islands are home to the two largest radiations: the *Celmisia* group with c. 160 species
460 and the *Raoulia* alliance with 42 species. On oceanic islands, the largest radiations are the Poly-
461 nesian *Bidens*, with 42 species distributed across Hawai'i, Marquesas, Society, and Austral Islands,
462 followed by the Hawaiian Silversword alliance with 33 species and the woody *Sonchus* alliance with
463 c. 31 species radiating on Macaronesia. The mean crown age of the radiations ranges from 0.4 to
464 24.18 million years (Myr), but the majority of radiations for which a crown age is available are
465 younger than 5 Myr, confirming that they represent mostly recent diversification events.

466
467 Asteraceae have radiated across a wide geographic range of islands, with radiations found on
468 large continental islands (e.g. *Apodocephala-Lowryanthus* on Madagascar) to oceanic archipelagos
469 (e.g. *Scalesia* on the Galápagos) to archipelagos with mixed geologic origin (e.g. *Anastrophia* on
470 the Caribbean), and from tropical islands (e.g. *Hesperomannia* on Hawai'i) to sub-Antarctic islands
471 (e.g. *Pluerophyllum* across the Auckland, Campbell, and Antipodes Islands, which is nested in the
472 larger *Celmisia* group radiation). The majority of confirmed radiations have occurred on oceanic
473 islands (26/39 radiations, Figure 5), and while our mixed effects models support the strong, posi-
474 tive association of isolation on endemism, this could also be a reflection of previous island research
475 focusing on oceanic systems. While radiations have occurred worldwide, several regions are notably
476 rich in confirmed radiations. At least seven radiations with a total of 302 species have occurred
477 on New Zealand and outlying Subantarctic islands. Macaronesia and the Hawaiian Islands also
478 disproportionately support a high number of Asteraceae radiations, with at least 10 radiations of
479 120 species total on Macaronesia, and six radiations comprising 90 species on Hawai'i. If we also
480 consider putative radiations, the number of radiation in these two regions increases to 15 and 8
481 respectively.

482
483 Despite the high number of confirmed radiations, it is only when surveying the putative radi-
484 ations that we begin to see the remarkable degree to which this family has, potentially, speciated
485 across islands. In our review, we identified 69 putative radiations, which range in size from three to
486 67 species (Table SD4). In general, many of the putative radiations are found within geologically-
487 complex regions or fall within large, taxonomically-complex clades. More specifically, several re-
488 gions have a high number of putative radiations. The Caribbean is a known hotspot of Asteraceae
489 diversity (Francisco-Ortega et al., 2008). We identified four confirmed radiations that were rep-
490 resented in a well-sampled phylogeny and 26 putative radiations with an overall total of c. 351
491 species. Madagascar is a hyper-diverse island with high endemism and Asteraceae are one of the
492 five most species-rich plant families composing the island's flora (Antonelli et al., 2022); we found
493 two confirmed radiations on Madagascar and identified 16 putative radiations that require future
494 phylogenetic work to investigate and delineate. Additionally, while several genera on Madagascar

495 (i.e. *Helichrysum*, c. 110 endemic species; *Senecio*, c. 50 endemic species; *Vernonia*, c. 70 endemic
496 species) meet our criteria of a putative radiation, they were not included in the putative radiation
497 list because these genera are known to be taxonomically complex (paraphyletic and polyphyletic)
498 and distinguishing the potential radiation from multiple colonization events, even tentatively, is
499 too challenging without a well-sampled phylogeny (Galbany-Casals et al., 2014; Pelsner et al., 2010;
500 Keeley et al., 2007; Siniscalchi et al., 2019).

501

502 Basing the assessment of putative radiations on taxonomy alone has the potential to under-
503 and over-estimate the number of island radiations. On the one hand, an under-estimate of the
504 number of radiations can occur when numerous island endemics within a single large genus arise
505 from multiple independent colonization events and subsequent radiations. For example, phyloge-
506 netic work on *Psiadia* on the Indian Ocean islands supports two independent radiations on the
507 Mascarenes (Strijk et al., 2012). On the other hand, an over-estimation can occur when numerous
508 small island-endemic genera are actually part of one larger island radiation. This can lead to two
509 assessment errors: the small island endemic genera inflate the putative number of radiations if they
510 meet the threshold criteria of three endemic species or the size of the actual radiation is obscured
511 when the small endemic genera are segregated out based on the taxonomy. For example, the
512 woody *Sonchus* alliance on Macaronesia comprises 6 genera, but from a well-resolved phylogeny
513 (Kim et al., 1996) we know these genera all arose from a single colonization event and radiated
514 across Macaronesia. Notwithstanding these considerations, our assessment of putative radiations
515 not only shows the potential magnitude of radiations within the family but also provides direction
516 for future phylogenetic research on island diversification.

517

518 The combination of confirmed and putative radiations totals to 108 island radiations within the
519 family, indicating that Asteraceae have the remarkable capacity to radiate across a wide diversity
520 of islands, including oceanic islands and continental islands, islands and archipelagos with varying
521 degrees of area and isolation, and across a wide spectrum of island ecosystems and habitat types.
522 How the overall number of island radiations within Asteraceae compares to other flowering plant
523 families still remains unknown because a comparable analysis of island radiations has not been
524 conducted. In a recent review (Cerca et al., 2023) that was restricted to adaptive radiations on
525 oceanic islands, Asteraceae stood out as the family with the highest number of adaptive radiations
526 (finding 19 radiations) compared to all taxonomic groups (arthropods, birds, mollusks, plants, am-
527 phibians, and reptiles). Additionally, a recent review of island radiations in birds (Illera et al., In
528 press), using the same criteria, found 39 island radiations compared to Asteraceae's 108 radiations
529 (confirmed and putative). Together, these studies indicate Asteraceae may be exceptionally rich
530 in island radiations compared not only to other flowering plant families but also to other broader
531 taxonomic groups.

532

533 Ultimately, future research should aim to move from identifying radiations to processes un-
534 derling island diversification. To this end, for confirmed radiations, we examined several different
535 characteristics and traits that are often associated with plant diversification on islands. Out of
536 all traits reviewed, the only trait that reveals a strong link with radiations is woodiness. The
537 vast majority of confirmed radiations have at least one woody species, which is in agreement with
538 recent research that this trait could have a role in diversification (Nürk et al., 2019). A diversity of
539 dispersal syndromes - a key trait in determining island colonization - are represented in Asteraceae
540 island radiations, with wind dispersal (anemochory) most common on less isolated archipelagos
541 (e.g. Macaronesia) and bird dispersal (endozoochory and epizoochory) more common on isolated

A Asteraceae island radiations

Confirmed radiations evidenced by robust phylogeny; putative radiations by taxonomy and species checklist.

3 Largest island radiations

1 *Celmisia* group: 160 species; New Zealand & Subantarctic Islands (*Pleurophyllum speciosum*)

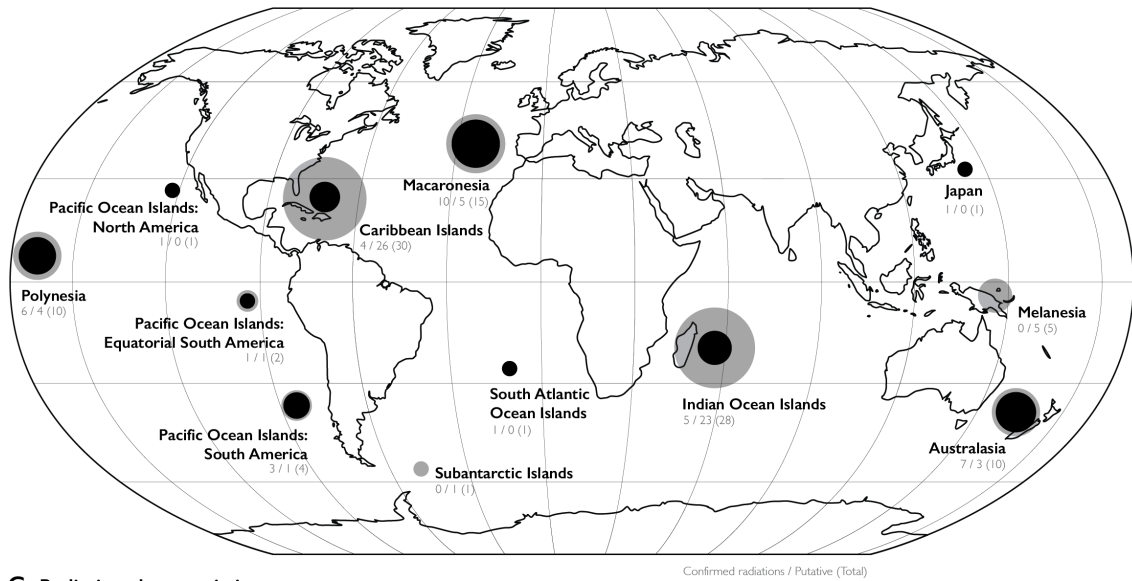

2 *Raoulia* alliance: 42 species; New Zealand, Chatham Islands, New Guinea (*Raoulia rubra*)

3 *Bidens*: 42 species; Polynesian Islands (*Bidens cosmoides*)

B Geographic range of island radiations

Comparison of the number of island radiations per region.

C Radiation characteristics

Characteristics and traits of the 39 confirmed radiations.

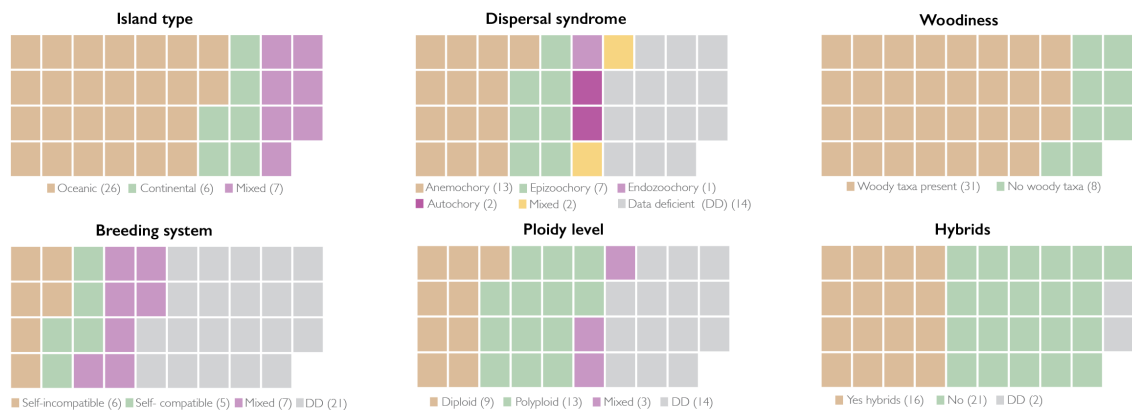

Figure 5: **Summary of island radiations within Asteraceae.** (A) Overview of the number of total, confirmed, and putative insular radiations within Asteraceae. The confirmed radiations have been evidenced by robust phylogenetic work and are represented by the black circles, and the putative radiations have been identified based on taxonomy and the island Asteraceae checklist and are represented by the gray circles (see methods for details on assessment criteria). Illustrations of species within the three largest island radiations. (B) Map compares the number of radiations between regions (defined in SD4); in cases where a radiation is distributed across multiple regions, it is included in the region where the most species diversity is located. Several island regions had no radiations (Mediterranean Islands, Micronesia) and are not included on the map. (C) The waffle charts summarize characteristics and traits of the confirmed radiations, where a single radiation is represented by one square. Traits were scored at the radiation level, and if there are multi-states in the radiation it is captured with the "Mixed" category. Full review of island radiations in Table SD4. Illustrations by Lizzie Roebble.

542 archipelagos (e.g. Polynesian islands). While self-compatibility is often cited to be over-represented
543 in island taxa (Grossenbacher et al., 2017; Pannell et al., 2015), in our review of breeding systems
544 (self-compatible, self-incompatible, or mixed), we found this trait to be surprisingly data deficient,
545 indicating fertile ground for more research.

546

547 Conclusion

548 Our analysis of the global patterns of diversity and distribution of Asteraceae on islands is an essen-
549 tial first step towards unlocking further research on Asteraceae on islands, moving beyond classic
550 well-studied oceanic islands (e.g., Canaries, Hawai'i) to cover less well-studied but also Asteraceae-
551 rich regions such as the Caribbean, New Guinea, or the Mascarenes. Asteraceae diversity is
552 unevenly distributed both geographically and across major clades in the family. This opens up the
553 question of what intrinsic traits and external abiotic conditions are driving Asteraceae diversity on
554 islands. The fact that Asteraceae follow key theoretical expectations of island biogeography and
555 macroecology, suggests that they are not an outlier governed by their own biogeographical rules,
556 highlighting their value as models for biogeography. In comparison with other groups, the key
557 advantage of Asteraceae may lie in its unusually large sample sizes in terms of species and radi-
558 ations, which may allow for circumventing a common limitation of studies of insular assemblages
559 that are typically species-poor. Finally, the large number of potentially undiscovered radiations of
560 Asteraceae suggests that many years of exciting discoveries on the evolution of this family lie ahead.

Supplementary data

Table SD1: **Global checklist of Asteraceae native and endemic to islands.** The global checklist of insular Asteraceae extracted from GIFT with subsequent manual curation is structured by island geographic units. For each island in the data set, we have a checklist of Asteraceae species, name standardization (original name, WCVP name, and GCD name status), reference to the primary source, intrafamily taxonomic classification, the floristic status of the species (native, endemic, non-endemic) to that geographic unit, distribution, and conservation status.

Table SD2: **References for the global island Asteraceae checklist.** References of the primary regional checklists and floras from the Global Inventory of Floras and Traits (GIFT) used to compile the global checklist of Asteraceae native and endemic to islands.

Table SD3: **Dataset of islands with the number of native and endemic Asteraceae species and associated abiotic variables used in the mixed effects models.**

Table SD4: **Review of confirmed and putative island radiations in Asteraceae.** The data includes (1) a literature review of the confirmed radiations with associated trait and characteristic data, (2) a literature review of the putative radiations with notes summarizing current phylogenetic work on the group and evidence supporting putative radiation status, (3) criteria for assigning radiation status (confirmed, putative) and key definitions, (4) references for both confirmed and putative radiations.

Supplementary material (Extended Data)

Table S1: **Comparison of candidate models for native species richness (NSR) and the proportion of single-island endemics (pSIE).** For both response variables (NSR and pSIE), we built a range of candidate models to evaluate the relationship between insular diversity and different island environmental parameter combinations. The final model for NSR and pSIE was selected based on the best AIC (Akaike information criterion), AICc (Akaike information criterion corrected for sample size), and BIC (Bayesian information criterion) scores and is highlighted in bold. In the model formulas, the abbreviations are defined as: dist = distance, SLMP = surrounding landmass proportion, itype = island type (oceanic or continental), mxelv = maximum elevation, TRI = terrain ruggedness index, anntemp = mean annual temperature, annprecip = mean annual precipitation, tempseas = temperature seasonality, precipseas = precipitation seasonality, arch = archipelago, zi = zero-inflation.

Model	Model type	AIC	AICc	BIC	R2 conditional	R2 marginal

Table S2: **Summary of the island diversity data for the top ten angiosperm families across all islands (continental, oceanic, and mixed) and oceanic islands.** The total number of species native to islands and total number of species endemic to islands was calculated from the GIFT checklist and the overall number of species within each family is based on the World Checklist of Vascular Plants (WCVP). Proportion insular species refers to the number of species within each family that are native to islands.

Family	Native island species	Endemic island species	Total species in family	Proportion insular species
<i>All islands</i>				
Orchidaceae	11,188	8,047	29,867	37%
Rubiaceae	6,188	4,740	14,083	44%
Asteraceae	6,135	3,535	33,994	18%
Fabaceae	4,169	1,773	22,187	19%
Poaceae	3,979	1,385	11,754	34%
Myrtaceae	2,389	1,808	6,186	39%
Cyperaceae	2,296	756	5,644	41%
Apocynaceae	2,288	1,633	6,487	35%
Euphorbiaceae	2,262	1,519	6,530	35%
Melastomataceae	1,954	1,617	5,844	33%
<i>Oceanic islands</i>				
Asteraceae	1,833	955	33,994	5%
Orchidaceae	1,776	708	29,867	6%
Poaceae	1,366	292	11,754	12%
Rubiaceae	1,343	871	14,083	10%
Fabaceae	1,141	287	22,187	5%
Cyperaceae	903	205	5,644	16%
Euphorbiaceae	653	287	6,530	10%
Myrtaceae	583	454	6,186	9%
Malvaceae	496	198	5,439	9%
Apocynaceae	480	256	6,487	7%

Table S3: **Binomial test for the ten most diverse angiosperm families on islands comparing the island proportion to the expected proportion of the family globally.** The total number of angiosperm species (n) on all islands is 99,659 species, and on oceanic islands 23,853 species. The sample estimate represents the estimated proportion of island species based on the observed data, and the 95% confidence interval is the range estimate for the true probability of success (i.e. the proportion of the family on islands). When the sample estimate is equal to the overall proportion of the family globally, the null hypothesis is accepted. The alternative hypothesis is accepted when the sample estimate is not equal to the overall proportion of the family globally, indicating a deviation from the expected proportion. If the sample estimate and 95% confidence interval are greater than the proportion of the family globally (p), then the family is more diverse on islands than expected, if they are lower than the proportion of the family globally, the family is less diverse on islands than expected given its global diversity.

Family	Binomial test parameters			Results	
	Native island species (x)	Proportion of family globally (p)	<i>p</i> -value	Sample estimate	95% confidence interval
<i>All islands</i>					
Orchidaceae	11,188	8.9	<0.001	11.23	11.03-11.42
Rubiaceae	6,188	4.2	<0.001	6.21	6.06-6.36
Asteraceae	6,135	10.2	<0.001	6.16	6.01-6.31
Fabaceae	4,169	6.6	<0.001	4.18	4.06-4.31
Poaceae	3,979	3.5	<0.001	3.99	3.87-4.12
Myrtaceae	2,389	1.9	<0.001	2.4	2.30-2.49
Cyperaceae	2,296	1.7	<0.001	2.3	2.21-2.40
Apocynaceae	2,288	1.9	<0.001	2.3	2.20-2.39

Table S5: **Binomial test for the tribes in Asteraceae comparing the island proportion to the expected proportion of the tribe globally.** The total number of Asteraceae species (n) on islands is 6,135 species. The sample estimate represents the estimated proportion of island species based on the observed data, and the 95% confidence interval is the range estimate for the true probability of success (i.e. the proportion of the tribe on islands). When the sample estimate is equal to the overall proportion of the tribe in Asteraceae (p), the null hypothesis is not rejected. The alternative hypothesis is accepted when the sample estimate is not equal to the overall proportion of the tribe globally, indicating a deviation from the expected proportion. If the sample estimate and 95% confidence interval are greater than the proportion of the tribe globally (p), then the tribe is more diverse on islands than expected, if they are lower than the proportion of the tribe globally, the tribe is less diverse on islands than expected given its global diversity. Significant deviations from the null expectation are highlighted in red (below expectation) and blue (above expectation).

Table S8: **Summary statistics for the native species richness on archipelagos generalized linear model.** In our global model for native species richness (Figure 4, Table S6), we found that the inclusion of archipelago as a random effect contributes substantially to the overall variance captured by the model (i.e. 0.56 marginal R^2 / 0.90 conditional R^2). To test the robustness of our general results, we aggregated the diversity and environmental data from the island level to the archipelago level and ran a generalized linear model. At the scale of the archipelago, the main model patterns do not change: area and isolation are the strongest predictors of native species richness, and the relationships between native species richness and environmental predictors remain the same. Notably for this model the marginal R^2 becomes 0.751, an increase from the 0.56 from the earlier model.

Native species richness (archipelago-level)			
<i>Predictors</i>	<i>Log-Mean</i>	<i>CI</i>	<i>p</i>
Intercept	3.49	3.21 – 3.76	<0.001
Area	0.85	0.60 – 1.09	<0.001
Isolation	-0.43	-0.62 – -0.24	<0.001
Island type [mixed]	-0.67	-1.83 – 0.50	0.262
Island type [oceanic]	-0.30	-0.70 – 0.10	0.141
Max elevation	0.27	0.03 – 0.51	0.026
Temperature seasonality	0.40	0.21 – 0.58	<0.001
Observations	139

DHARMA residual

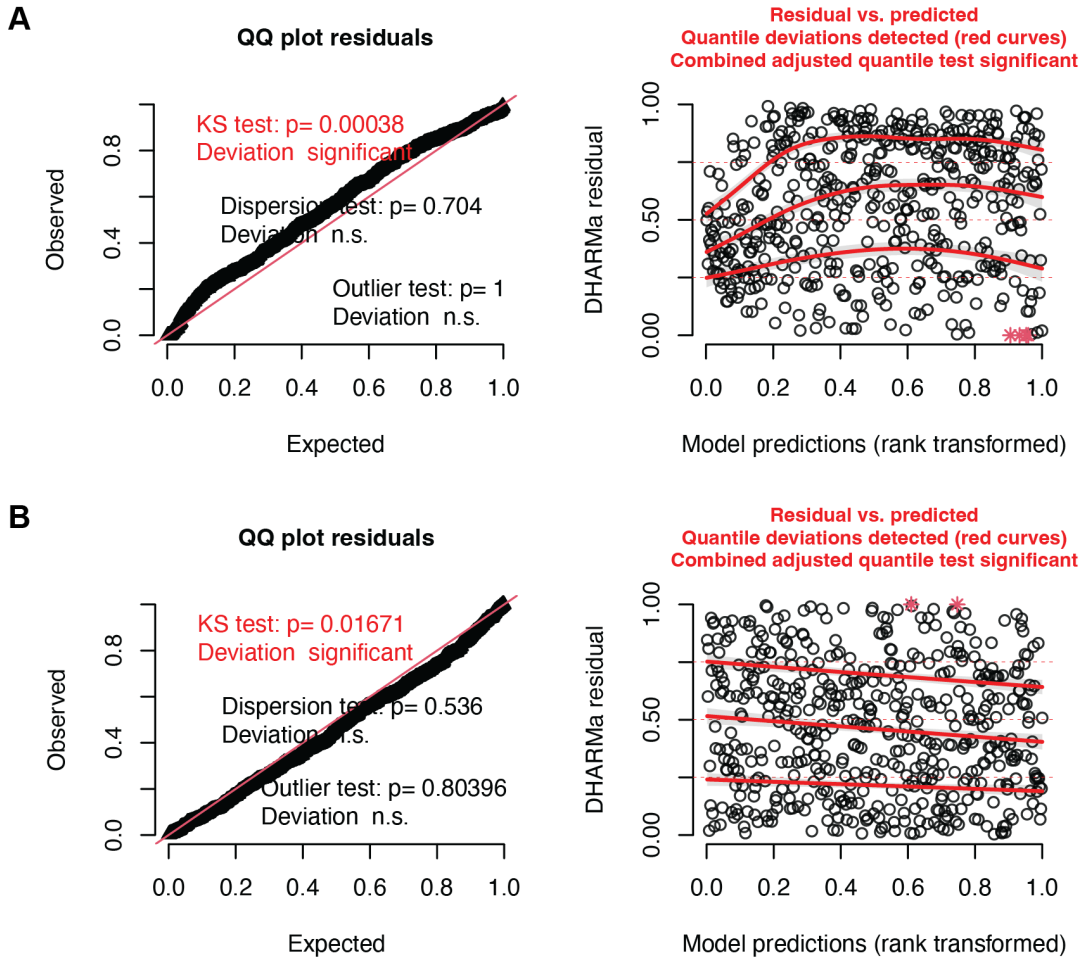

Figure S1: **Diagnostic plots of the scaled residuals for the fitted models for (A) Native species richness and (B) Proportion of single-island endemics.** We assessed the scaled residuals with the DHARMA package (Hartig, 2022), which simulates standardized residuals from the fitted model and can check for overdispersion and zero inflation. The QQ plots (left panel) detect deviations from the expected distribution, dispersions, and outliers; the residuals plot (right panel) shows the simulated residuals against the predicted values. For the NSR model (A), no significant outliers or overdispersion were detected. The simulated residuals indicate that the NSR model has difficulties predicting native species numbers for islands with a low number of native species (1-3) well. In particular, the model tends to overestimate these numbers. This is likely a reflection of sampling bias, where islands without any native species presence were filtered out of the data set and islands with few species possibly being poorly sampled locations or capturing possibly native (e.g. introduced species) species. Although deviations are marked as significant, they do not appear to be large. Furthermore, adding quadratic terms, splines or additional interactions did not significantly change the observed patterns. For the pSIE model (B), no significant outliers or overdispersion were detected. The simulated residuals for pSIE indicate heteroscedasticity but the effect is mild.

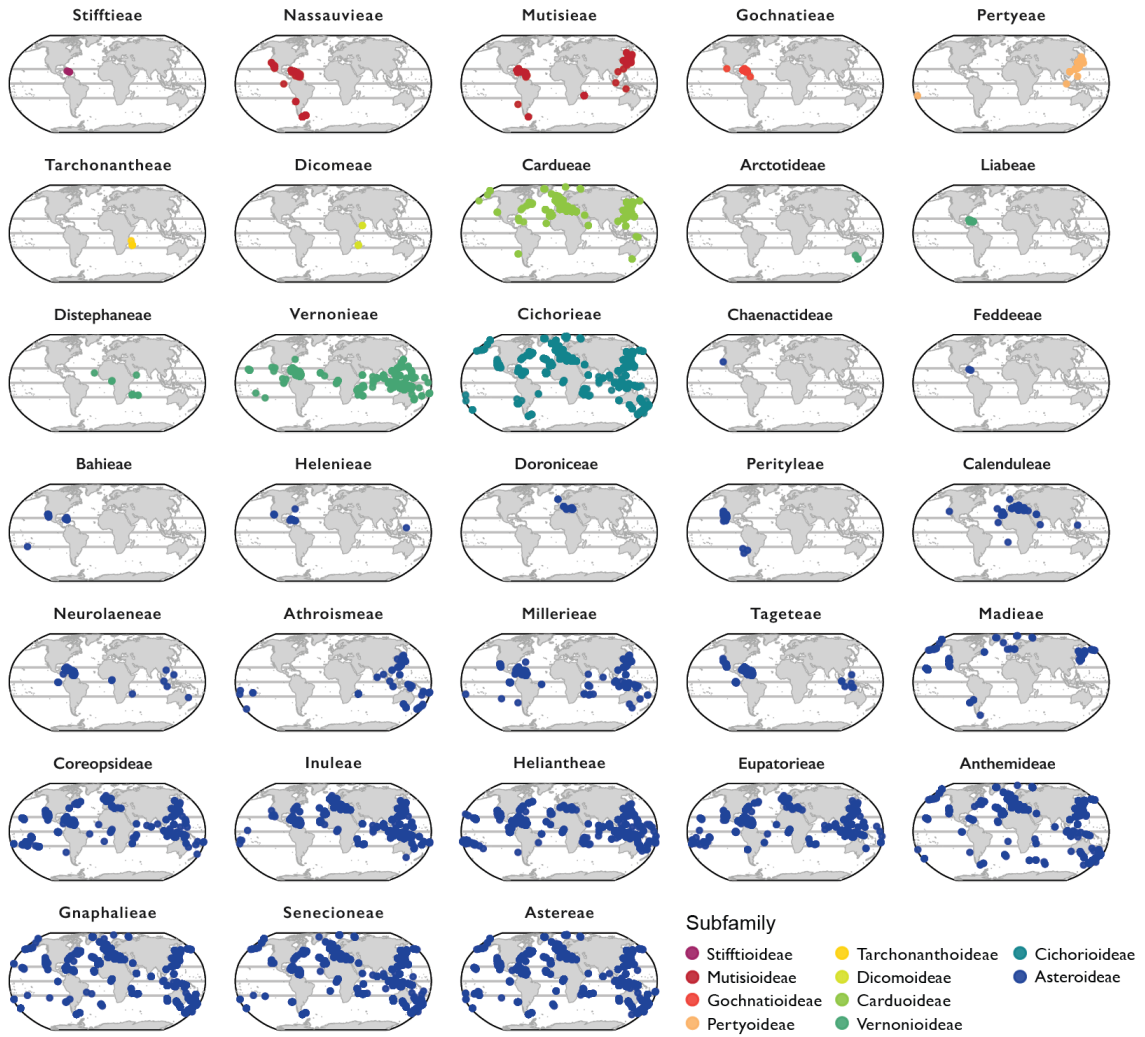

Figure S2: **Geographical distribution of native species on islands per tribe.** The tribes are colored and grouped by their subfamily.

Figure S3: Standardized coefficients for the island age subset models. Coefficient estimates for the subset of global models for (A) native species richness (blue) and (B) the proportion of single-island endemics (green) including Age+Age² as an additional fixed effect. The bars around the coefficient estimates represent the standard error. The dark gray vertical intercept at 0 indicates no significant effect, and island variables with a positive coefficient estimate indicate an increase in native species richness or proportion endemism, whereas a negative coefficient estimate indicates a decrease in the response variables.

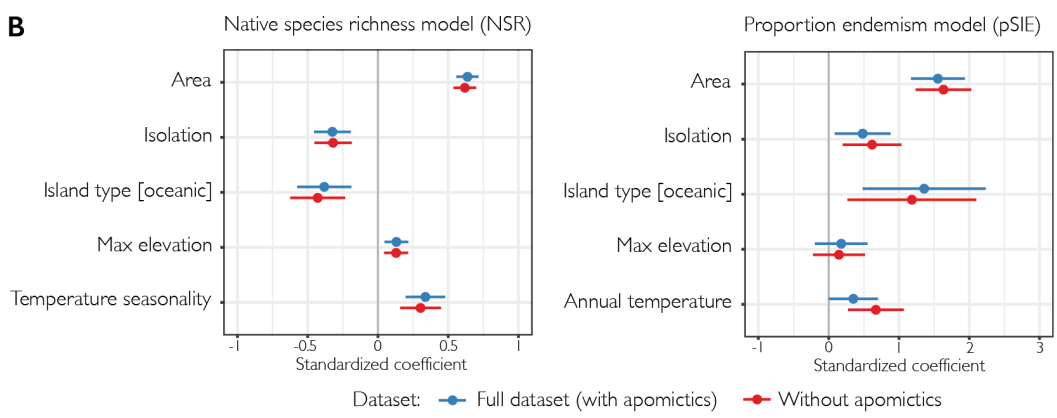

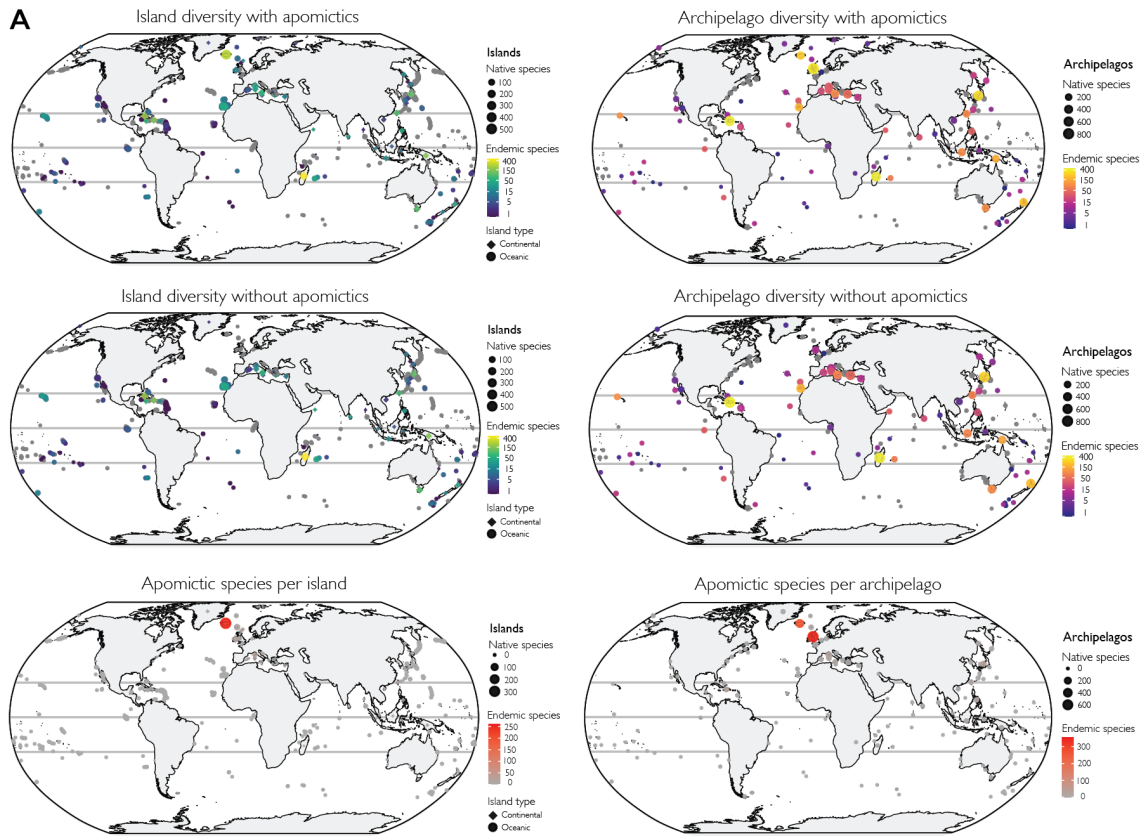

Figure S4: Impact of apomictic species on family-level diversity analyses. (Caption next page.)

Figure S4: **Impact of apomictic species on family-level diversity analyses.** (Previous page.) Here we evaluate the influence of apomictic species on family-level diversity analyses, focusing on two aspects: (1) geographic distribution and hotspots, and (2) island biogeographic patterns. Apomictic genera were filtered based on the Apomixis Database (<https://www.uni-goettingen.de/de/apomixis+database/423360.html>), an online database containing information on apomixis at the genus level in angiosperms. We examine the difference in diversity pattern using two datasets: one including all genera even putative apomictics (full dataset), and another with apomictic genera removed. (A) Geographic distribution and hotspots: The top row of maps presents the distribution with the full dataset on islands (left) and archipelagos (right), the middle row shows the distribution with apomictics excluded, and the third row shows the number of putative apomictic species per insular unit (island or archipelago). Most islands have no change in diversity due to apomictics, but the largest differences are on Iceland and the British Isles. (B) Island biogeographic patterns: we ran and compared generalized linear mixed effects models with both the full dataset and filtered dataset with apomictic genera removed to test whether the same global model was selected for both. There was no change in the best global model with the filtering of apomictics. We fit the global model for both datasets, and (in B) compare the standardized coefficients for the full dataset (blue) and dataset with apomictics removed (red). There is no significant change in predictor relationships when apomictic genera are removed.
