40

41 **Abstract**

42 1. Freshwater microbial communities are essential for maintaining ecosystem functions
43 and services, with aquatic fungi playing a particularly critical role in decomposing
44 terrestrial organic matter entering streams and converting it into energy and nutrients
45 that sustain higher trophic levels. However, freshwater ecosystems face growing threats
46 from multiple stressors. The combined effects of these stressors on fungal biodiversity
47 and functioning in streams remain poorly understood. This study examines the joint
48 effects of land-use and climate-driven stressors on fungal biodiversity and two key
49 functions—fungal biomass accrual and organic matter decomposition—across two
50 stream compartments: the water column and streambed sediments.

51 2. We conducted an extensive two-year survey across 62 Iberian stream sites in
52 southwestern Europe. To assess stressor impacts, we analysed responses from both the
53 water column and streambed sediments, examining compartment-specific differences.
54 Models were developed to evaluate six stressor types - organic matter and inorganic
55 nutrient enrichment, oxygen depletion, thermal stress, drying stress and riparian
56 degradation- and hydrology. Fungal responses were evaluated across multiple
57 biodiversity dimensions, including taxonomic diversity, functional diversity, and
58 community composition.

59 3. Results revealed that organic matter enrichment positively influenced fungal
60 biodiversity and functioning, while thermal and drying stresses, along with riparian
61 degradation, had significant negative effects. Stressor effects were predominantly
62 additive, with limited interactions observed. Inorganic nutrient enrichment showed weak
63 effects, likely reflecting minimal nutrient limitation in Iberian streams. Differences
64 between stream compartments emerged, with streambed sediments buffering the
65 negative impacts of thermal and drying stresses on fungal biodiversity and functions.

66 4. Our findings underscore the influence of multiple stressors on fungal biodiversity and
67 functioning, which are expected to intensify under climate change. The predominance of
68 additive stressor effects suggests that individual stressors can be targeted
69 independently, simplifying management strategies. The buffering role of streambed
70 sediments highlights their importance in providing resilience against global stressors,
71 particularly thermal and drying stresses.

72 5. This study emphasises the urgent need to safeguard conditions that support fungal
73 biodiversity and ecosystem functions in streams to ensure the continued provision of vital
74 ecosystem services in the face of global change.

75

76 **1. Introduction**

77 Stream ecosystems are vital for sustaining biodiversity, regulating biogeochemical cycles, and
78 promoting human well-being (Aufdenkampe et al., 2011; Lynch et al., 2023; Tickner et al.,
79 2020). However, freshwater ecosystems are increasingly threatened by multiple stressors that
80 adversely affect riverine biota and ecosystem functioning (Carpenter et al., 2011; Reid et al.,
81 2019). A stressor is defined as any abiotic variable that, when altered by human activities,
82 results in significant changes in riverine biota or ecosystem functioning (Birk et al., 2020;

83 Sabater et al., 2019). Simultaneous alterations in multiple abiotic factors can produce
84 cumulative ecological impacts that are challenging to predict when each factor is considered
85 individually (Birk et al., 2020; Rillig et al., 2023; Sabater et al., 2019), especially at the scale
86 of food-webs or ecosystems (Bruder et al., 2019). Consequently, there has been an increasing
87 focus on studies investigating the combined effects of co-occurring stressors (e.g., David et
88 al., 2024; Graça et al., 2024). However, most of these studies are limited to small-scale
89 observational or experimental settings, limiting our ability to identify general patterns that could
90 inform biomonitoring and restoration efforts (Gutiérrez-Cánovas et al., 2022; Orr et al., 2024;
91 Rillig et al., 2023). Therefore, it is essential to develop studies that address realistic gradients
92 of multiple stressors and incorporate large spatial scales to better understand general
93 responses of stream biodiversity and functions to global change (Johnson & Penaluna, 2019).

94 On a global scale, stream ecosystems receive, process, and transport approximately 1.9 Pg
95 of terrestrially derived carbon annually (Cole et al., 2007). Many headwater streams rely on
96 terrestrial carbon inputs to sustain their food webs and key ecosystem functions, such as
97 organic matter (OM) decomposition and the transfer of energy to higher trophic levels
98 (Gessner et al., 2010; Vannote et al., 1980). Microbial communities, particularly fungi, are key
99 biotic drivers of these processes, playing a central role in carbon cycling by decomposing large
100 amounts of OM entering streams (Gessner et al., 2007). The functional importance of fungi in
101 streams is supported by strong positive associations between fungal biodiversity, reproduction
102 (e.g., conidial production), biomass production, and OM decomposition rates, particularly for
103 coarse particulate OM, such as leaves and wood (Arias-Real et al., 2022; Fenoy et al., 2021;
104 Gessner, 1997). These positive biodiversity effects arise through increased efficiency due to
105 wider niche representation and complementarity in diverse fungal communities or due to the
106 presence of highly performing species (Duarte et al., 2006; Geraldès et al., 2012).

107 The pivotal role of aquatic fungi in stream ecosystems can be compromised by global change
108 drivers, including land-use intensification and the climate crisis. Agriculture and urbanisation
109 impact streams through organic and inorganic nutrient enrichment, oxygen depletion, and
110 riparian degradation, among other impacts (Bruno et al., 2016; Carpenter et al., 1998; Colls et
111 al., 2024). While the links between catchment management and stream biodiversity are well-
112 documented for organisms commonly used in biomonitoring (e.g., macroinvertebrates,
113 diatoms, macrophytes; Feld et al., 2018; Hering et al., 2006), there is limited understanding of
114 how land-use stressors interact with climate-driven impacts to affect fungal biodiversity and
115 functions in streams. For example, rising thermal and drying stresses in stream ecosystems
116 may amplify the impact of nutrient enrichment and riparian degradation (Birk et al., 2020;
117 Graça et al., 2024; Soria et al., 2020), leading significant challenges for ecological
118 management and mitigation.

119 Previous research has revealed contrasting effects of individual stressors on fungal
120 communities and associated functions. For instance, moderate inorganic nutrient enrichment
121 and warming often enhance fungal activity and OM decomposition (Biasi et al., 2017; Fenoy
122 et al., 2016, 2024; Fernandes et al., 2012; Ferreira & Graça, 2016; Martínez et al., 2014) or
123 show no response (Bruder et al., 2016). However, studies addressing broader stressor
124 gradients suggest more complex, non-linear relationships. For example, a non-linear
125 relationship between nutrients and OM decomposition, with decomposition rates peaking at
126 intermediate inorganic nutrient levels (Pereira et al., 2016; Woodward et al., 2012). Similarly,
127 when considering wider water temperature gradients (4-22°C), fungal functional diversity
128 declined at higher temperatures (Fenoy et al., 2021). In addition, dissolved organic carbon

129 enrichment can stimulate fungal biomass and growth in the water column (Jørgensen &
130 Stepanauskas, 2009; Wurzbacher et al., 2014). In contrast, stressors such as oxygen
131 depletion and drying reduce fungal diversity and inhibit fungal production, biomass, and
132 reproduction (Abril et al., 2016; Arias-Real et al., 2022; Gomes et al., 2018; Graça et al., 2024).
133 Since aquatic hyphomycetes rely on dissolved oxygen and water availability for OM
134 decomposition, their activity declines monotonically under hypoxic and drying conditions
135 (Bruder et al., 2011; Medeiros et al., 2009).

136 Riparian degradation, including the loss of plant diversity and cover, also influences fungal
137 community composition and activity by reducing the quality and quantity of OM inputs
138 (Fernandes et al., 2013; Laitung & Chauvet, 2005; Tonin et al., 2018). However, the effects of
139 increased light availability due to riparian canopy loss are mixed, with studies reporting both
140 positive and negative outcomes (Ashberry et al., 2021; Danger et al., 2013; Tonin et al., 2018).
141 Thus, addressing the combined effects of multiple stressors under realistic ecological
142 conditions is essential to understanding their cumulative impacts on stream ecosystems.

143 The effects of stressors also vary across stream compartments, reflecting differences in their
144 stability and vulnerability to human impacts (Burrows et al., 2017; Gonçalves et al., 2019;
145 Solagaistua et al., 2015). For instance, previous studies suggest that microbial biodiversity
146 and functions within streambed sediments generally show greater resistance to stressors than
147 those in the water column. This “insurance capacity” may be attributed to the reduced
148 exposure of sediments to environmental extremes, such as solar radiation and drying (Arias-
149 Real et al., 2022; Gionchetta et al., 2024), and could enable stream ecosystems to face human
150 impacts more effectively than expected. However, under global change scenarios where
151 multiple stressors co-occur, little is known about how their combined effects influence
152 ecosystem functions across different stream compartments, such as the water column and
153 streambed sediments. Understanding these dynamics is critical to informing management and
154 restoration actions that aim to enhance stream resilience and resistance to anthropogenic
155 impacts.

156 In this study, we explore the combined effects of land-use and climate-driven stressors on
157 fungal biodiversity and two key functions — fungal biomass accrual and OM decomposition
158 (Abril et al., 2021; Ferreira & Graça, 2006)— across different stream compartments. Using
159 data from an extensive two-year survey of 62 Iberian streams sites (southwestern Europe),
160 we investigated these functions in both the water column and streambed sediments to capture
161 potential differences in stressor impacts between ecosystem compartments. Our models
162 considered the effects of six types of stressors — organic and inorganic nutrient enrichment,
163 oxygen depletion, thermal stress, drying stress, riparian degradation—and hydrology, a critical
164 factor for stream biodiversity and functioning (Abril et al., 2021; Ferreira & Graça, 2006).
165 Fungal responses were evaluated across multiple biodiversity facets, including taxonomic and
166 functional diversity and community composition.

167 **2. Methods**

168 **2.1 Study area and sampling design**

169 The study was conducted in 62 stream sites across the Iberian Peninsula between 2022 and
170 2023. Thirty-six sites were surveyed twice within this period, whereas the remaining 27 sites
171 were surveyed once. The surveyed watercourses were in seven regions representing
172 contrasting climatic conditions, differing primarily in annual aridity and mean air temperature

173 (Figure 1; Table S1). The Andalusia, Catalan, and Segura regions are characterized by arid
174 and warm climatic conditions, while the Cantabrian Mountain Range and North Portugal
175 exhibit more humid and cooler climates. The Mid Tagus and South Douro regions experience
176 intermediate levels of aridity, with the South Douro region having the lowest mean air
177 temperatures among the studied areas. Lithology varied across the regions: the Cantabrian,
178 Catalonian, and Segura areas were predominantly calcareous, whereas siliceous bedrocks
179 dominated in the Mid Tagus, North Portugal and South Douro regions. Andalusia presented a
180 mix of sedimentary and siliceous lithologies.

181 In each region, we selected nine stream sites covering crossed gradients of land-use
182 intensification and reach-scale riparian vegetation cover to capture a wide range of organic
183 and inorganic nutrient enrichment, oxygen depletion, thermal stress, riparian degradation,
184 drying stress and stream hydrology (Table S2). The sampling design was intended to
185 represent realistic gradients of multiple abiotic factors that could act as stressors for stream
186 ecosystems (Brauns et al., 2022; Gutiérrez-Cánovas et al., 2022; Lourenço et al., 2023). We
187 define stressors as any abiotic variable that, when altered by human intervention, results in
188 significant changes in riverine biota or ecosystem functioning (Birk et al., 2020; Sabater et al.,
189 2019).

190 By capturing different land-use intensifications and climate settings, our sites cover long
191 gradients of abiotic stress, including dissolved nitrate (DN; 0.01–28.81 mg L⁻¹), dissolved

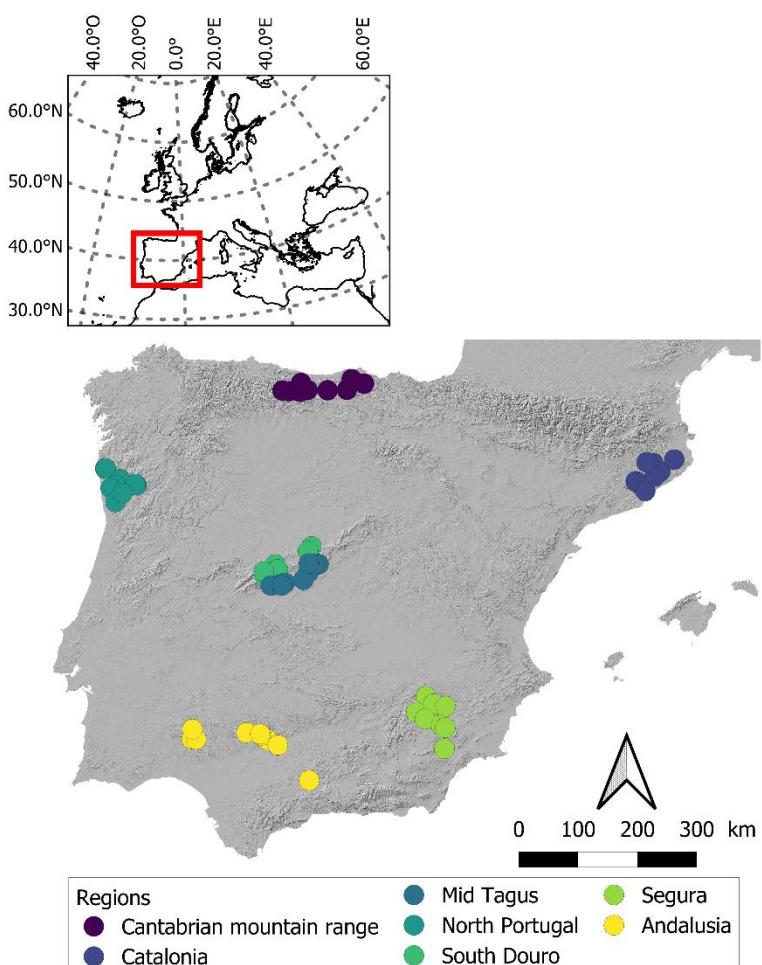

Figure 1. Locations of the study sites within the Iberian Peninsula and their context within Europe (red square).

reactive phosphorous (SRP; 0.4–2138.2 µg L⁻¹), dissolved organic carbon (DOC; 0.9–233.9 mg L⁻¹) and dissolved oxygen (DO) concentration deficit (-1.68–6.35 mg L⁻¹). Variations in site elevation (10–1.537 m.a.s.l.), riparian canopy openness (0–96%) and local climate (annual mean air temperature: 9.4–18.5°C) permitted us to capture a wide range of daily mean water temperatures (10.7–28.3°C). Hydrological conditions also varied widely, including gradients of both discharge (0–914 L s⁻¹) and drying stress (0–134 dry days). These gradients represent a spectrum of stress intensities and combinations, simulating realistic global change scenarios related to land-use intensification and climate change (Table S1), and are comparable to those used in manipulative experimental studies (e.g., Cross et al., 2022; Matthaei et al., 2010; Romero et al., 2018).

We conducted a field experiment at each stream, starting in late spring and continuing through summer. Initially, we characterised the stressors and fungal communities (see sections 2.2 and 2.3, respectively) and deployed organic matter substrates (wooden sticks). Subsequently, in the following autumn or winter of each year, the wooden sticks were retrieved to assess OM decomposition and fungal biomass accrual (see section 2.4). This strategy allowed us to capture the period of maximum biological activity and stressor levels (e.g., thermal stress, oxygen depletion and dry stress, which tend to peak during summer).

2.2 Stressor and environmental gradients

At each sampling site, we characterised indicators of organic and inorganic nutrient enrichment, oxygen depletion, thermal stress, riparian degradation, drying stress, and stream hydrology (Table S1). To assess gradients of organic matter and inorganic nutrients, water samples were filtered in the field through pre-washed glass fibre filters with a 0.7-µm pore size (Whatman, UK). Dissolved nitrate (DN) and soluble reactive phosphorus (SRP) were used as proxies for inorganic nutrient enrichment. The filtered water samples for inorganic nutrient analysis were stored in plastic vials and kept frozen until laboratory analysis. Inorganic nutrient concentrations were determined using standard colourimetric methods (APHA, 1995; FUTURA Autoanalyzer, Frepillon, France). Dissolved organic carbon (DOC) was used as a proxy for organic matter enrichment. DOC samples were acidified, stored in glass vials, and kept cold until analysis. DOC concentrations were measured using high-temperature catalytic oxidation (TOC/TN analyser, Shimadzu Corp., Kyoto, Japan) after sparging to remove dissolved inorganic carbon.

We calculated mean daily dissolved oxygen (DO) deficit in the water column as an indicator of oxygen depletion and hypoxic conditions, which can enhance anaerobic respiration (Blaszcak et al., 2023; Gómez-Gener et al., 2020). DO was recorded every 10 minutes over at least 24 hours using miniDOT loggers (PME, USA) placed at a depth of 10–30 cm and secured to the streambed with iron bars. The DO deficit was calculated as the difference between the saturation concentration and the mean daily DO concentration.

Mean water temperature was recorded continuously during the study periods (89–212 days) using HOBO MX2201 loggers (Onset, USA) and used as an indicator of thermal stress. To characterise drying stress, we measured the drying duration (dry days), which was inferred from variations in the diel range of water temperature and field visits following Arias-Real et al., 2020. Abrupt increases in diel temperature range indicated streambed drying, allowing us to capture the duration of the dry period.

To determine riparian canopy openness, indicative of riparian degradation, we used the Gap Light Analysis Mobile Application (GLAMA) from five hemispheric photographs taken along a

237 100-m site. To characterise hydrology and control for catchment and stream size, we
238 measured discharge. Discharge was calculated as the product of mean width, mean depth,
239 and mean current velocity across five transects over a 100-m site. For each transect, we
240 recorded at least five measures of depth and current velocity using a flow meter and graduated
241 sticks.

242 Our environmental dataset included some missing values for DN (n=4), SRP (n=5), DOC
243 (n=13), DO deficit (n=8), water temperature (n=33) and drying stress (n=33) due to absence
244 of water (stream desiccation), equipment malfunctions, or sample loss. Missing values for DN,
245 SRP, DOC, DO deficit, and water temperature were imputed using linear-mixed effects
246 models, except for DOC, where a linear regression model was statistically better supported.
247 Methodological details and results are available in Appendix 1. In brief, for each response
248 variable and based on previous knowledge (nutrients: Dodds & Oakes, 2004; Shen et al.,
249 2020; DOC: Catalán et al., 2018; Granados et al., 2022; DO deficit: Blaszcak et al., 2023;
250 Gutiérrez-Cánovas et al., 2024; water temperature: Kamarianakis et al., 2016; Segura et al.,
251 2015), we produce a full model including spatial (latitude and longitude), temporal (sampling
252 year), land-use (percentage of agricultural and urban cover), climatic (mean annual air
253 temperature), riparian degradation (riparian canopy openness), and/or hydrological
254 (discharge) factors. We evaluated each model's performance using explained variance by
255 fixed factors (r^2_m) and a 10-fold cross-validation. Models explained moderate to high amounts
256 of variance: 37.2% for DN, 38.8% for SRP, 69.1% for DOC, 48.4% for DO deficit, and 80.1%
257 for water temperature. Missing data for drying days were imputed using field information about
258 water presence from pre- and post-summer field visits conducted between 2022 and 2024.

259 2.3 Fungal biodiversity

260 To assess the biodiversity of aquatic fungal communities, foam samples for the identification
261 of aquatic fungi (mainly aquatic hyphomycetes) were collected during the summers of 2022
262 and 2023. Fresh foam from the surface of stream water was collected using a spoon,
263 transferred to plastic tubes, and fixed with 96% ethanol. An aliquot was filtered through 5 µm
264 pore-size cellulose nitrate filters (Merck, Germany). The retained conidia were stained with a
265 0.1% trypan blue solution in lactic acid and examined under a light microscope (400x). Spores
266 of aquatic hyphomycete species were identified to the lowest possible taxonomic level and
267 counted based on conidial morphology (Gulis et al., 2020). In total, 122 taxa were identified,
268 representing 57 genera, 22 families, and 16 orders. Twenty taxa could not be identified and
269 were therefore included only in the taxonomic analyses but excluded from the functional ones.

270 Functional traits of fungal species were compiled, including six traits based on previous efforts
271 (Arias-Real et al., 2023; Table 1). Specifically, we characterised traits such as primary lifestyle,
272 decay substrate, habitat, capacity to inhabit tree-holes, endophyte capacity, and conidial
273 morphology. These traits encompassed 20 categories for 98 species out of the 122 taxa
274 identified.

Table 1. Fungal traits, their corresponding categories, and the references used for their definition.
The table is adapted from Arias-Real et al. (2023) with additional references included.

275

276 To characterise the taxonomic diversity of fungal communities, we calculated taxon richness,
 277 representing the number of taxa in each community. Additionally, we characterized two
 278 measures of functional-trait diversity: functional richness (FRic), which estimates the range of
 279 trait variation within a community (Villéger et al., 2008), and functional dispersion (FDis), which
 280 represents the variability in trait composition within a community (Laliberté & Legendre, 2010).

281 To calculate FRic and FDis, we built a principal coordinate analysis (PCoA) based on a fuzzy-
 282 coded adapted Gower dissimilarity matrix (Pavoine et al., 2009) derived from the six fungal
 283 traits, including all their categories. The functional space generated from this analysis
 284 represented trait variation across fungal species. The first five axes, explaining 81.7% of the
 285 Gower dissimilarity matrix, were retained to ensure adequate representation of the five-
 286 dimensional space (Maire et al., 2015). To quantify functional composition, we estimated the
 287 community centroids for the first two axes by calculating the mean position of the occurring
 288 species along these axes.

289 **2.4 Organic matter decomposition and fungal biomass accrual**

290 To quantify the decomposition of OM in the different stream compartments five tongue
 291 depressor sticks ($15 \times 2 \times 0.2$ cm) made of *Populus x canadensis* wood were placed on top
 292 of the streambed to characterise decomposition in the water column, while another five sticks
 293 were buried vertically beneath the streambed to characterise decomposition in the streambed
 294 sediments (Arroita et al., 2012). All wooden sticks were pre-marked and weighed. Wooden
 295 sticks provide a standardised and chemically untreated material, making them ideal for
 296 decomposition experiments (Arroita et al., 2012).

297 In the water column, each group of sticks was inserted into the holes of a brick to prevent
 298 exposure to sunlight and algae growth. The brick was secured to metal bars using nylon

299 threads, branches, or roots to ensure its position within the lotic habitat. During installation, we
300 ensured that the sticks were fully submerged in the water. In the streambed sediments, each
301 group of sticks was buried in the sediment and similarly tied to metal bars with nylon thread.
302 The sticks were placed at each site in late spring or summer of 2022 and 2023, an average
303 time of 147 days (range: 89-212 days).

304 To prevent ergosterol degradation and potential weight changes during wooden stick
305 collection, the sticks were stored in zip-lock bags, transported in dark, refrigerated containers,
306 and processed immediately upon arrival at the laboratory. Each stick was brushed to remove
307 adhered material and washed with distilled water. A 1-cm section was cut from each stick and
308 frozen at -80 °C for later ergosterol determination as a proxy for fungal biomass accrual
309 (Gessner, 2020). The remaining portion of each stick was dried at 70 °C for 72 hours, weighed,
310 and summed to the frozen aliquot fraction for ergosterol measurement (see below).

311 Decomposition rates were calculated using the negative exponential equation $M_t = M_0 \cdot e^{-kt}$,
312 where M_0 is the initial dry mass, M_t is the remaining dry mass at time t , and k is the decay rate
313 (Bärlocher, 2020). Decomposition rates were not corrected for temperature to assess the
314 impact of thermal stress in our models. Additionally, the percentage of remaining mass, the
315 decay rate, and the temperature-corrected decay rate exhibited a strong positive correlations
316 for each compartment ($r_p=0.88-0.97$), indicating minimal influence of the methodological
317 choice.

318 To calculate the fungal biomass accrual, we measured the ergosterol concentration at each
319 stick. First, frozen aliquots of sticks were lyophilised and weighed. Second, lipid extraction and
320 saponification were performed using 0.14 M KOH in methanol (8 g L⁻¹) in a shaking bath at
321 80 °C for 30 minutes. Solid-phase extraction cartridges (Waters Sep-Pak® Vac RC, 500 mg
322 tC18, Waters Corp, Milford, MA, USA) were used to purify lipid extracts, with ergosterol eluted
323 using isopropanol. High-pressure liquid chromatography (HPLC; Jasco HPLC system, USA)
324 was used to detect and quantify ergosterol at 282 nm with a Gemini-NX 5 µm C18 250 × 4.6-
325 mm column (Phenomenex, UK). Finally, ergosterol was converted into fungal biomass using
326 a conversion factor of 5.5 mg of ergosterol per gram of fungal mycelium (Gessner & Chauvet,
327 1993). Results were expressed as mg of fungal biomass per gram of OM dry mass.

328 To examine whether the effects of multiple stressors on fungal decomposition and biomass
329 accrual differ across compartments, we calculated the ratio of decomposition and fungal
330 biomass accrual between the streambed sediment and water column.

331 **2.5 Data analysis**

332 To explore the effects of multiple stressors on fungal biodiversity metrics and functions, we
333 used linear mixed-effects models (LMMs) and linear regression models (LMs), following a
334 multi-model inference approach (Burnham & Anderson, 2004). All models included all eight
335 predictors representing the six stressor gradients and hydrology (see before): DN, SRP, DOC,
336 oxygen deficit, thermal stress (mean water temperature), riparian canopy openness, drying
337 stress and discharge.

338 A three-step process was employed for multi-model inference. First, we evaluated whether to
339 include a random intercept (site) to account for the dependence structure, as 36 sites were
340 surveyed twice during the study period. Using the functions *lmer()* from the *lme4* R package
341 and *lm()*, we fitted two models for each response variable, one with and one without the
342 random factor. We calculated the Akaike information criterion for small sample sizes (AICc),

343 the explained variance by the random factor (Nakagawa & Schielzeth, 2013), and evaluated
344 the occurrence of singular fits. Random factor was retained if they improved model fit (lower
345 AICc values, higher variance explained, and no singular fits). As a result, we fitted mixed-
346 effects models for all variables except for fungal biomass accrual in streambed sediments,
347 decomposition in streambed sediments, FDis and functional community centroids, for which
348 linear regression models were applied (Appendix 2).

349 Second, AICc was used to determine whether global models for each response variable
350 should include pairwise interaction terms besides the additive stressor terms. When a model
351 including an interaction has a lower AICc value than the pure additive model, we used the
352 *anova()* function to evaluate if retaining the model with the interaction leads to a significant
353 gain of explanatory capacity. A recent synthesis revealed that inorganic nutrient enrichment is
354 an overarching stressor for riverine ecosystems, which can interact with light, thermal and
355 hydrological stressors across spatial scales (Birk et al., 2020). Thus, we tested three related
356 interactive terms where inorganic nutrient enrichment effects can be modulated by thermal
357 stress ($DN \times$ water temperature), riparian degradation ($DN \times$ riparian canopy openness) or
358 drying ($DN \times$ drying). Additionally, we tested the interaction between drying and canopy
359 openness to evaluate whether higher riparian cover mitigates the impacts of drying by
360 retaining moisture and maintaining fungal activity (Gionchetta et al., 2020).

361 Third, for each response variable, we quantified stressor coefficients, statistical support, and
362 importance using the function *dredge()* from the *MuMIn* R package (Bartoń, 2024). This
363 function generates models for all potential combinations of predictors included in the global
364 selected model. Models were ranked based on AICc, and those within $\Delta AICc \leq 7$ of the top-
365 ranked model were retained (Burnham et al., 2011). We calculated explained variance by fixed
366 factors (r^2_m) and by fixed and random factors (r^2_c). For each response variable and model, we
367 derived Akaike weights to determine the explanatory power and the relative likelihood of each
368 model (statistical support), respectively. Akaike weights were also used to calculate mean-
369 weighted variance explained by each predictor (Hoffman & Schadt, 2016). To visualise the
370 overall response of these models and using model's Akaike weights, we calculated a
371 weighted-average of their standardized regression coefficients and predictions across the
372 retained models ($\Delta AICc \leq 7$). Model residuals were visually assessed to verify linear model
373 assumptions. All statistical analyses were performed using R (v4.2.2, R Development Core
374 Team, 2022).

375 **3. Results**

376 **3.1 Multiple stressor effects on fungal biodiversity**

377 The three most common taxa were *Alatospora acuminata* Ingold 1942 (63.0% of sites),
378 *Hymenoscyphus tetracladius* Abdullah, Descals & Webster 1981 (53.7%), and *Tetracladium*
379 *marchalianum* De Wild. 1893 (51.9%; Table S3). Fungal assemblages in northern Portugal
380 exhibited the highest taxonomic richness (Ric; mean \pm SE: 14.4 ± 1.46 taxa), whereas the
381 Segura and Andalusia regions showed the lowest values (8.9 ± 1.8 and 8.3 ± 0.9 taxa,
382 respectively; Figure 2a & Table S4). For functional richness (FRic), the Segura, Tagus and
383 Douro regions displayed the highest mean values (FRic; 0.67 ± 0.08 , 0.62 ± 0.07 , and $0.61 \pm$
384 0.04, respectively; Figure 2b), while the Andalusia and Catalonia regions exhibited the lowest
385 mean functional richness (0.32 ± 0.09 and 0.26 ± 0.00 , respectively). In contrast, functional
386 dispersion (FDis) showed similar mean values across regions, with the highest value in the
387 Douro region (0.36 ± 0.03 ; Figure 2c) and the lowest in the Catalonia region (0.20 ± 0.04).

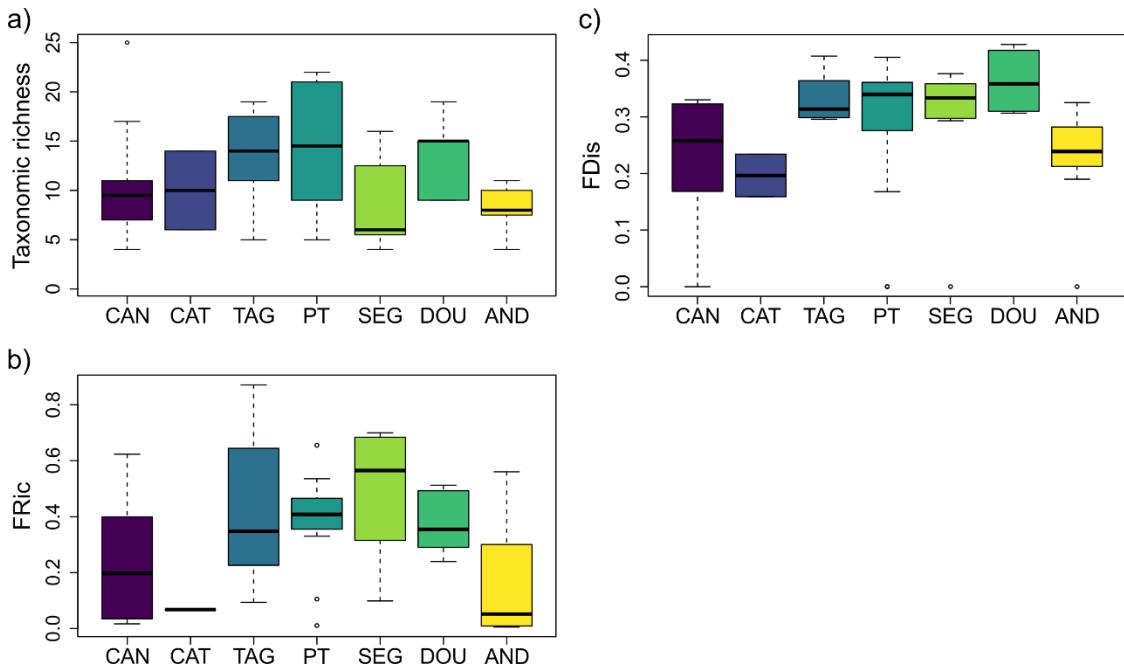

Figure 2. Boxplots showing the variation in (a) taxonomic richness, (b) functional richness (FRic), and (c) functional dispersion (FDis) across the study regions. Region abbreviations: CAN – Cantabrian Mountain Range, CAT – Catalonia, TAG – Mid Tagus, PT – North Portugal, SEG – Segura, DOU – South Douro, and AND – Andalusia.

388 The first and second axes of the functional space for fungal communities explained 30% and
 389 23% of the variance, respectively. The first axis represents a trade-off between wood and leaf
 390 decomposers (Table S5). This axis was positively correlated with primary lifestyle as wood
 391 saprotrophic ($r_P=0.69$), wood as the decay substrate ($r_P=0.60$), and primary lifestyle as plant
 392 pathogenic ($r_P=0.59$). In contrast, it was negatively correlated with primary lifestyle as litter
 393 saprotrophic ($r_P=-0.89$) and litter as the decay substrate ($r_P=-0.69$). The second axis
 394 represented differences in habitat preferences and conidial shape, showing a positive
 395 correlation with the capacity to inhabit tree-holes ($r_P=0.53$) and branched conidial shape
 396 ($r_P=0.51$). Conversely, it was negatively correlated with non-aquatic habitat ($r_P=-0.80$) and
 397 tetraradiate conidial morphology ($r_P=-0.58$).

398 Our models predicting fungal biodiversity responses to multiple stressors generally indicated
 399 additive responses (Figure 3). Trait-based metrics were generally more responsive than
 400 taxonomic richness (Tables S6 & S7).

401 Taxonomic richness was negatively associated with water temperature ($R^2 = 1.7\%$).
 402 Functional richness (FRic) was positively related with discharge ($R^2=2.5\%$), SRP ($R^2=2.2\%$),
 403 DOC ($R^2=1.8\%$), and DO deficit ($R^2=1.6\%$). Functional dispersion (FDis) showed a positive
 404 correlation with DO deficit ($R^2=6.7\%$) and DOC ($R^2=4.5\%$), but a negative response to water
 405 temperature ($R^2=5.5\%$) and drying duration ($R^2 = 1.0\%$). The mean centroid of the first
 406 functional axis (wood vs leaf decomposers) was positively related with SRP ($R^2=8.3\%$) and
 407 water temperature ($R^2=7.2\%$), but correlated negatively with DO deficit ($R^2=1.3\%$). Functional
 408 axis 2 (habitat preferences and conidial morphology) had a positive relationship with discharge
 409 ($R^2=2.6\%$) and drying duration ($R^2=2.5\%$), while it responded negatively to riparian canopy
 410 openness ($R^2=5.1\%$).

411 3.2 Multiple stressor effects on fungal ecosystem functioning

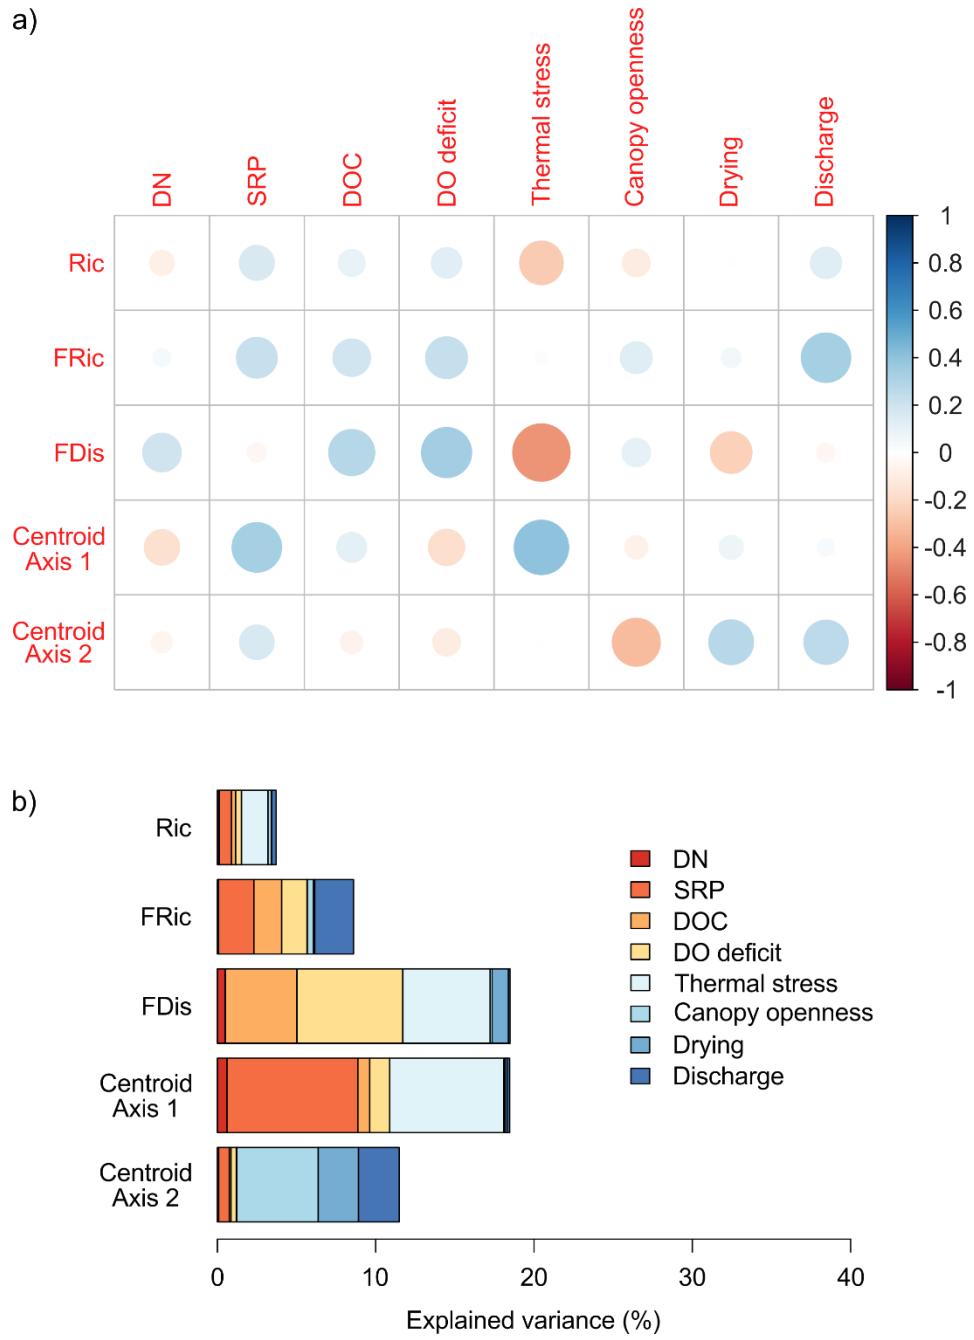

Figure 3. (a) Averaged and standardised model coefficients for the different fungal biodiversity facets, including taxonomic richness (Ric), functional richness (FRic), functional dispersion (FDis), and centroids of the first and second trait axes (Axis 1 and Axis 2). Red tones represent negative predictor effects, while blue tones indicate positive effects. (b) Mean explained variance of stressors and hydrology for the different fungal biodiversity facets, including taxonomic richness (Ric), functional richness (FRic), functional dispersion (FDis), and centroids of the first and second trait axes (Axis 1 and Axis 2). The random factor importance is not shown for simplicity (see further details in Table S7).

412 The greatest decomposition rates in the streambed sediment and water column compartments
 413 were found in the Cantabrian Mountains ($0.0048 \pm 0.0006 \text{ day}^{-1}$, $0.0038 \pm 0.0006 \text{ day}^{-1}$, respectively) and Catalonian regions ($0.0045 \pm 0.0006 \text{ day}^{-1}$, $0.0034 \pm 0.0006 \text{ day}^{-1}$),
 414 while the other regions had lower mean values (Figure 4 & Table S8). Decomposition rates
 415 were greater in the water column ($0.0033 \pm 0.0002 \text{ day}^{-1}$) compared to the sediment ($0.0029 \pm 0.0002 \text{ day}^{-1}$). In the water column, the Tagus and Cantabrian regions showed the highest
 416
 417

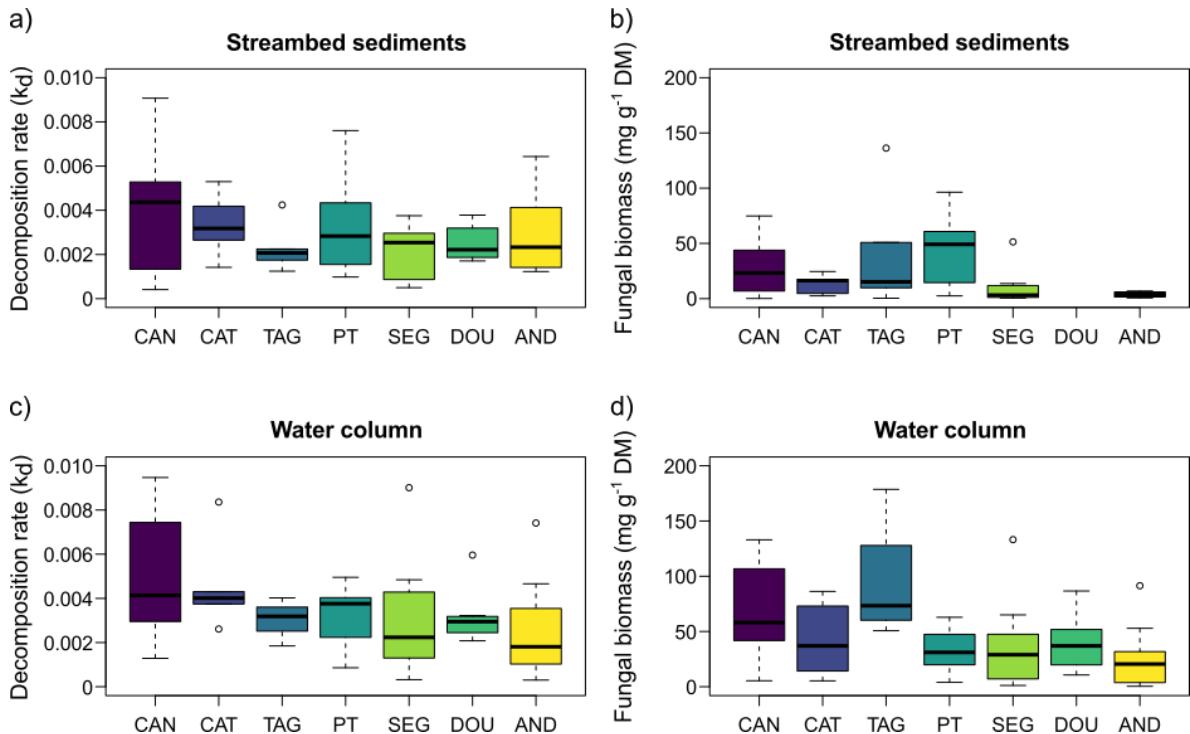

Figure 4. Boxplots of: (a) decomposition rate (k_d) in the water column, (b) decomposition rate (k_d) in the streambed sediments, (c) fungal biomass in the water column, and (d) fungal biomass in the streambed sediments. The colours of the bars correspond to the regions (as shown in Figure 1). Region abbreviations are as follows: CAN, Cantabrian Mountain range; CAT, Catalonia; TAG, Mid Tagus; PT, North Portugal; SEG, Segura; DOU, South Douro; and AND, Andalusia.

418 mean fungal biomass ($94.0 \pm 19.2 \text{ mg FB g DM}^{-1}$ and $66.9 \pm 9.9 \text{ mg FB g DM}^{-1}$, respectively),
 419 while the Segura ($34.5 \pm 8.0 \text{ mg FB g DM}^{-1}$), northern Portugal ($32.9 \pm 4.3 \text{ mg FB g DM}^{-1}$),
 420 and Andalusia ($23.8 \pm 5.6 \text{ mg FB g DM}^{-1}$) regions exhibited the lowest values. In contrast, the
 421 northern Portugal region exhibited the highest mean fungal biomass in streambed sediments
 422 ($44.3 \pm 7.1 \text{ mg FB g DM}^{-1}$), followed by the Tagus region ($42.5 \pm 18.6 \text{ mg FB g DM}^{-1}$). The
 423 Segura and Andalusia regions showed the lowest mean fungal biomass in streambed
 424 sediments ($9.7 \pm 3.9 \text{ mg FB g DM}^{-1}$ and $3.8 \pm 0.7 \text{ mg FB g DM}^{-1}$, respectively). On average,
 425 fungal biomass in the water column compartment ($47.6 \pm 9.6 \text{ mg g}^{-1}$) was double that in
 426 streambed sediments ($23.6 \pm 6.6 \text{ mg FB g DM}^{-1}$).

427 Our models generally supported additive stressor effects on ecosystem functions and the
 428 sediment: water column ratios, with only one interactive term supported in the model of
 429 streambed sediment fungal biomass (Figure 5; Tables S5 & S6). Water column decomposition
 430 was positively associated with DOC ($R^2 = 7.0\%$) and SRP ($R^2 = 7.0\%$) but decreased with
 431 drying duration ($R^2 = 9.7\%$) and water temperature ($R^2 = 4.3\%$). In contrast, streambed
 432 sediment decomposition was primarily driven by the positive effects of DOC enrichment ($R^2 =$
 433 22.9%). The sediment: water column ratio for the decomposition rate was positively related to
 434 DOC ($R^2 = 5.7\%$), drying duration ($R^2 = 1.7\%$) but negatively related to SRP ($R^2 = 6.9\%$).

435 The fungal biomass in the water column compartment was positively associated with DOC (R^2
 436 = 8.5%) and DN ($R^2 = 1.4\%$), while it had a negative relationship with water temperature (R^2
 437 = 13.0%), riparian canopy openness ($R^2 = 7.6\%$), and drying duration ($R^2 = 3.3\%$). Fungal
 438 biomass in the sediments was positively associated with DOC ($R^2 = 9.5\%$), DO deficit ($R^2 =$
 439 4.9%), and discharge ($R^2 = 9.6\%$), but was negatively affected by water temperature ($R^2 =$
 440 5.3%) and DN (1.7%). An antagonistic interaction between drying duration and DN enrichment

441 was statistically supported, explaining 5.3% of the variance. The sediment: water column ratio
 442 for fungal biomass was positively related to drying duration ($R^2 = 6.3\%$), water temperature
 443 ($R^2 = 1.6\%$), and discharge ($R^2 = 1.2\%$), but showed a negative correlation with DN ($R^2 = 3.7\%$)
 a)

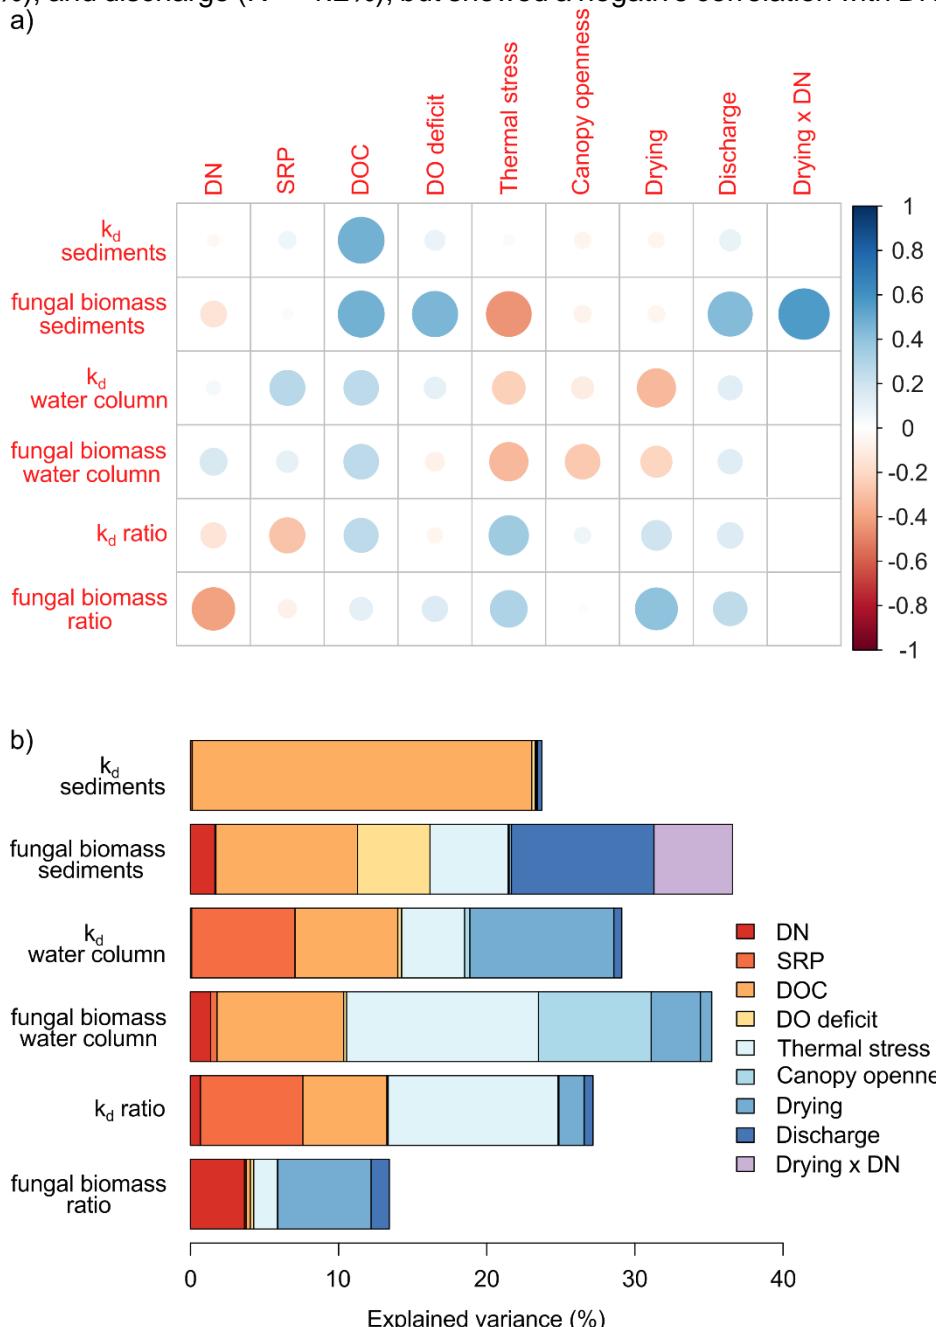

Figure 5. (a) Averaged and standardised model coefficients for the decomposition rate (k_d) and fungal biomass in the water column and streambed sediment. Red tones represent negative predictor effects, while blue tones indicate positive effects. (b) Mean explained variance of stressors and hydrology for the decomposition rate (k_d) and fungal biomass in both stream compartments. For simplicity, the importance of random factors is not shown here (see Table S7 for further details).

444 (Figure 5).

445 **4. Discussion**

446 Our results demonstrate that fungal communities and their functions are shaped by multiple
 447 abiotic drivers, offering valuable insights into the effects of global change on stream

448 ecosystems. Specifically, while DOC positively influenced biodiversity and ecological
449 functions, water temperature, riparian canopy openness, and drying duration were associated
450 with lower biodiversity and functionality. These findings highlight the critical role of climatic
451 stressors in regulating stream microbial biodiversity and function, suggesting that climate
452 change may significantly reduce fungal biodiversity, decomposition activity, and trophic
453 transfer. Additionally, we found that stream sediments can sustain OM decomposition and
454 fungal biomass accrual, even under stressors, such as thermal and drying stress, providing
455 an “insurance capacity” against human impacts.

456 **4.1 Multiple stressor effects on fungal biodiversity and functions**

457 Our study identified DOC, water temperature, riparian canopy openness, and drying duration
458 as key drivers of fungal biodiversity and functions. Organic matter enrichment, represented
459 here by DOC, positively influenced fungal diversity and functions, likely due to its ability to
460 enhance heterotrophic microbial activity, including that of aquatic fungi (Danger et al., 2016;
461 Kuehn et al., 2014). Furthermore, in our study, higher DOC levels were associated with a
462 higher occurrence of wood saprotrophs, suggesting that dissolved carbon may originate from
463 the decomposition of deadwood, potentially from deciduous tree species (Błońska et al.,
464 2019).

465 Conversely, increasing water temperature was associated with reduced fungal biodiversity
466 and functions, except in sediment decomposition. Within our thermal stress gradient (10.7–
467 28.3°C), this negative response may be related to the fact that aquatic fungal communities
468 exhibit their highest species richness in temperate streams (Duarte et al., 2016), within an
469 optimal temperature range of 15 – 25°C (Graça et al., 2023; K. Sridhar & Bärlocher, 1993;
470 Suberkropp, 1984). Additionally, species richness typically follows a unimodal relationship with
471 temperature, peaking at around 10°C (Duarte et al., 2017; Gonçalves et al., 2013). Studies
472 reporting positive temperature effects have generally focused on gradients ranging from below
473 to near-optimal conditions (Fernandes et al., 2009; Ferreira, Chauvet, et al., 2015), with such
474 patterns being more consistent during colder months (Ferreira & Canhoto, 2014, 2015). In
475 contrast, our study was conducted during summer, when the mean water temperature of most
476 streams exceeded this optimal range, reaching the upper end of the thermal gradient (10.7–
477 28.3°C). This was particularly evident in the Andalusian (mean: 21.9°C, range: 17.8–28.3°C),
478 Catalan (19.7°C, 17.8–21.3°C) and Segura (17.5°C, 13.3–21.8°C) basins, which showed the
479 lowest biodiversity values and generally reduced functional metrics. These findings align with
480 previous studies that reported reductions in functional richness across broader water
481 temperature gradients (4–22°C) (Fenoy et al., 2021).

482 Consistent with previous observational and manipulative research, drying stress – particularly
483 prolonged drying – negatively affected fungal functional diversity and functions in water
484 column compartments (Arias-Real et al., 2020, 2023; Viza et al., 2022). Flowing water is
485 essential for the sporulation and dispersal of aquatic hyphomycetes (Bärlocher, 1992b).
486 Although microbial decomposers, including aquatic hyphomycetes, often recover their activity
487 quickly following rewetting events (Bruder et al., 2011; Foulquier et al., 2015; Niyogi et al.,
488 2020; Pohlon et al., 2013), our results suggest that prolonged drying during summer
489 consistently inhibits their biological activity across regions.

490 Our results also indicated that riparian degradation, represented by riparian canopy openness,
491 was generally associated with reduced fungal biodiversity and functions. Streams with
492 reduced riparian forest diversity and cover are expected to experience declines in the quality

493 and quantity of OM inputs (Kominoski et al., 2011), as well as more severe summer conditions
494 with increased water temperatures and radiation inputs (Garner et al., 2017). This reduction
495 in OM availability may lower fungal biodiversity and activity through bottom-up effects, as
496 reduced resource availability, which simplifies the range of niches available for these
497 organisms (Fernandes et al., 2013; Laitung & Chauvet, 2005; Tonin et al., 2018).

498 The effects of light availability further illustrate the complexity of riparian degradation. Field
499 studies have shown varied outcomes, with some reporting no significant impact (Elosegi et
500 al., 2018) and others highlighting negative effects, potentially due to increased solar radiation
501 inhibiting fungal activity under open canopies (Albariño et al., 2008; Tonin et al., 2018). In
502 addition, the absence of canopy cover reduces OM availability and background biomass of
503 litter-associated communities (Oester et al., 2025). Experimental mesocosm studies have also
504 yielded mixed findings. Some suggest a positive priming effect, where increased light
505 enhances autotrophic production and labile OM availability, thereby stimulating fungal growth
506 and accelerating OM decomposition (Danger et al., 2013; Lagrue et al., 2011; Rier et al.,
507 2007). Conversely, other mesocosm studies report negative priming, where labile carbon from
508 algal exudates suppresses the decomposition of recalcitrant carbon (Ashberry et al., 2021;
509 Halvorson et al., 2019).

510 Surprisingly, and in contrast to previous research (Gulis et al., 2006; Menéndez et al., 2011;
511 Pascoal et al., 2005; Pereira et al., 2016), nutrient enrichment was not identified as a dominant
512 driver of fungal functions, possibly reflecting low nutrient limitation in Iberian rivers (Bruder et
513 al., 2016). Our nutrient enrichment gradients were skewed towards higher concentrations,
514 largely due to arid climates and pervasive agricultural activities. As a result, we may not have
515 captured scenarios where moderate increases in nutrient concentrations stimulate fungal
516 activity and diversity. Furthermore, our study was conducted in summer, when temperatures
517 are higher compared to other seasons, and at elevated temperatures, fungal decomposer
518 activity appears to be achieved at much lower nutrient levels (Fernandes et al., 2014). In
519 regions with high agricultural activity, additional stressors, such as sedimentation and
520 pesticides, may reduce decomposer activity despite higher nutrient concentrations (Pascoal
521 et al., 2005; Pereira et al., 2016; Woodward et al., 2012). A continental-scale study, including
522 colder regions and oligotrophic streams, found a non-linear relationship between nutrient
523 levels and OM decomposition, with macroinvertebrate-mediated decomposition rates peaking
524 at intermediate nitrogen and phosphorus concentrations (Woodward et al., 2012). Field
525 experiments often report weaker effects of nutrient enrichment compared to laboratory studies,
526 with variability influenced by substrate type (e.g., wood vs. leaf litter) and climate (Bruder et
527 al., 2016; Ferreira, Castagneyrol, et al., 2015). Our study underscores the importance of
528 considering a broad range of geographic conditions and multiple stressors for a more
529 comprehensive assessment of nutrient effects, which may be less pronounced than previously
530 suggested (Duarte et al., 2017; Woodward et al., 2012).

531 Nonetheless, nutrient enrichment generally had weak positive effects on taxonomic and
532 functional diversity metrics and fungal functions in the water column, with nitrogen showing
533 minimal impact (Ferreira & Graça, 2016; Lecerf & Chauvet, 2008). Enhanced decomposition
534 rates under nutrient-enriched conditions were linked to increased fungal activity (Gulis et al.,
535 2006; Menéndez et al., 2011; Pascoal et al., 2005), as fungi can absorb nutrients directly from
536 the water column (Sridhar & Bärlocher, 2000; Suberkropp & Chauvet, 1995). In contrast,
537 nutrient enrichment negatively affected fungal decomposition and biomass accrual in
538 streambed sediments, likely due to reduced oxygen availability caused by summer flow

539 reductions and fine sediment deposition from agricultural activities (Bruder et al., 2016).
540 Although this mechanism was not directly measured, it warrants further investigation.
541 Additionally, nitrogen was correlated with litter saprotrophs, while SRP was associated with
542 wood saprotrophs, indicating substrate-specific nutrient limitations (Danger et al., 2016).

543 Our study also supports the idea that microbial activity can be maintained in sediments even
544 in the presence of multiple stressors. Previous studies in intermittent streams hypothesised
545 that sediment moisture acts as a refuge for aquatic fungi during drying events, preserving
546 microbial activity at levels comparable to those under flowing conditions (Arias-Real et al.,
547 2020; Ghate & Sridhar, 2015; Gionchetta et al., 2024; Schreckinger et al., 2021). Riparian
548 shading and flash storms further enhance this "insurance capacity" by maintaining sediment
549 water content and detrital resources (Gionchetta, Oliva, et al., 2019; Herbst, 1980).
550 Additionally, our data suggest that streambed sediments can buffer extreme temperatures and
551 protect microbial activity during extreme climatic events, while slight to moderate organic
552 matter enrichment can stimulate the development of heterotrophic microbial biomass,
553 supporting higher activity levels in sediments than in the column water (Gionchetta, Oliva, et
554 al., 2019). However, microbial communities may respond differently according to their
555 taxonomic group, with fungi being the least affected by hydrological alterations (Gionchetta,
556 Romaní, et al., 2019).

557 Discharge positively influenced fungal functional diversity and functions, with a notable
558 correlation to basin area (Figure S1). Sites with higher average discharge tend to have fewer
559 periods or areas of dry conditions, thereby maintaining aquatic functions (Bruder et al., 2011).
560 Higher discharge also buffers against temperature extremes, particularly in summer, by
561 increasing the thermal capacity of the water column through a greater volume of water
562 (Caissie, 2006). Additionally, higher flow velocities, associated with increased discharge,
563 enhance fluxes of dissolved nutrients and oxygen, thereby stimulating fungal diversity and
564 activity, such as sporulation and decomposition rates (Abril et al., 2016; Bruder et al., 2016;
565 Ferreira & Graça, 2006).

566 **4.2 Implications for stream management and biomonitoring in a global change 567 context**

568 Despite the prevalence of antagonistic interactive effects in experimental studies (Gutiérrez-
569 Cánovas et al., 2022; Jackson et al., 2016; Velasco et al., 2018), our findings reinforce a
570 growing body of literature suggesting that the combined effects of multiple stressors in real-
571 world ecosystems tend to be additive rather than interactive (Birk et al., 2020; Gutiérrez-
572 Cánovas et al., 2022; Lourenço et al., 2023). Notably, our analysis did not support stressor
573 interactions, even though we captured long stress gradients (Feld et al., 2016; Segurado et
574 al., 2022), representing a wider spectrum of stress conditions than those typically explored in
575 experimental studies (Graça et al., 2023; Jackson et al., 2016).

576 Two reasons may explain these contrasting patterns between observational and manipulative
577 studies. First, manipulative studies are typically short-term and may not account for
578 acclimation, adaptation, recovery, or resilience mechanisms that occur over longer periods
579 (Collins et al., 2020; Orr et al., 2020). Second, while manipulative studies often apply stressors
580 simultaneously, stressor dynamics in natural ecosystems tend to occur sequentially or
581 discretely, enabling organisms to resist and recover more effectively (e.g. heatwaves, Jackson
582 et al., 2021). Fortunately, from a management perspective, non-interactive effects are among

583 the simplest to address, as stressors can be mitigated independently or in combination without
584 unintended side effects (Brown et al., 2013; Côté et al., 2016; Spears et al., 2021).

585 Organisms commonly used in biomonitoring programmes, such as diatoms, macrophytes, and
586 invertebrates, are particularly vulnerable to nutrient and organic pollution (Birk et al., 2020;
587 Hering et al., 2006). For this reason, most management actions focus on reducing nutrient
588 pollution and improving water quality. However, our study demonstrates that stressors
589 expected to intensify with climate change—such as warming, drying, and riparian
590 degradation—are more critical for fungal biodiversity and functions (Barros et al., 2024; Bruder
591 et al., 2016; Fenoy et al., 2021; Mora-Gómez et al., 2016). For example, climate change is
592 expected to negatively affect fungal biodiversity and functions through increased water
593 temperature (Tassone et al., 2023), prolonged drying (Messager et al., 2021), and riparian
594 canopy loss (Pace et al., 2021, 2022). Nonetheless, as organic matter enrichment was
595 positively associated with fungal biodiversity and function, climate change impacts may be
596 partially offset by anticipated increases in DOC under conditions of low flow and hydrological
597 fragmentation (Granados et al., 2022). Collectively, these findings suggest that mitigating
598 warming through riparian restoration and maintaining natural flow conditions are among the
599 most effective strategies for preserving fungal biodiversity and functions in a global change
600 context.

601 While previous studies have found that taxonomic and trait metrics respond similarly to
602 multiple stressors (Lourenço et al., 2023), our models indicate that functional trait diversity and
603 composition were much more explanatory than taxon richness. This may partly reflect the
604 large geographic scale of our study, where differences in taxonomic biogeography may blurry
605 ecological responses. However, as traits are shared across species with contrasting spatial
606 distributions, functional diversity and composition seems to be more robust tools for capturing
607 the impacts of global change on streams at large scales, aiding to capture broad biodiversity
608 response to environmental change.

609 Our study also offers insights into the advantages and limitations of using ecosystem functions
610 as biomonitoring indicators for multiple stressor effects. Although there have been recent calls
611 to incorporate ecosystem functioning into biomonitoring, few studies have evaluated their
612 response to multiple stressors in natural streams (Brauns et al., 2022; but see Pereira et al.,
613 2016; Smeti et al., 2019). While previous studies have suggested that aquatic fungi and their
614 activities, such as OM decomposition, can serve as bioassessment tools for stream
615 functioning—responding to hydromorphological alterations, nutrient availability, and pollution
616 levels (Barros et al., 2024; Colas et al., 2017; Ferreira et al., 2021)—our study surprisingly
617 found that decomposition and fungal biomass did not reflect changes in nutrient enrichment,
618 one of the main focuses of stream biomonitoring. Other studies have shown complex
619 responses of OM decomposition to nutrients (Woodward et al., 2012), ranging from strong
620 (Arroita et al., 2012) to weak effects (Brauns et al., 2022; Tiegs et al., 2024), suggesting that
621 these indicators may be less sensitive than invertebrates or diatoms for detecting nutrient
622 pollution. However, our functional measurements effectively captured hydroclimatic stressors
623 such as warming, drying, and riparian degradation, highlighting their potential to complement
624 traditional biomonitoring methods. Despite the cost-effectiveness of using wooden sticks to
625 estimate decomposition (Arroita et al., 2012), ergosterol analysis and result interpretation
626 require more sophisticated and expensive methodologies and expertise.

627 In conclusion, our study demonstrates that fungal biodiversity and functions are shaped by
628 multiple stressors, which are likely to intensify under climate change. While organic matter

enrichment positively influenced fungal biodiversity and functions, thermal and drying stresses, as well as riparian degradation, had negative effects. Importantly, our findings highlighted the critical role of streambed sediments in buffering the impacts of thermal and drying stresses, providing streams with resilience against global change. The predominance of additive (non-interactive) stressor effects suggests that these stressors can be managed independently, simplifying the implementation of targeted mitigation measures. Together, these results underscore the urgent need for action to preserve the conditions that support stream microbial biodiversity and their associated functions, thereby safeguarding the essential services provided by freshwater ecosystems in a global change context.

Author contributions

Conceptualisation: A.V., E.F., C.G.C., **Developing methods:** E.F., A.B., R.C., M.M. (fungal spore identification), A.V., R.A.R., I.M.-S., I.M. (decomposition, fungal biomass and fungal traits), A.L. (DOC and nutrient analyses), C.G.C. (coordination, study design and fieldwork protocol). **Conducting the research:** A.V., E.F., M.A., M.Á., R.A.R., C.A., J.B., A.B., R.C., Í.D., I.F., A.J.G.M., A.L., I.M.-S., M.M., I.M., C.P., M.T.M., C.G.C. **Data analysis:** C.G.-C. **Preparation of figures and tables:** A.V., C.G.C.; A.V. and C.G.-C. led the writing, and E.F., M.A., M.Á., R.A.R., C.A., J.B., A.B., R.C., Í.D., I.F., A.J.G.M., A.L., I.M.-S., M.M., I.M., C.P. and M.T.M. revised and edited the text, providing critical comments.

Acknowledgments

R.A.R. held a postdoctoral grant, "Juan de la Cierva" (JDC2022-048728-I), funded by the Spanish Ministry of Science and Innovation and the Next Generation EU. C.G.C. is supported by a Ramón y Cajal contract (RYC2022-038189-I), funded by the Spanish Ministry of Science, Innovation and Universities (MICIU) through the Spanish State Research Agency (AEI) (MICIU/AEI/10.13039/501100011033) and by the European Social Fund Plus (ESF+). This research was carried out with the support of a Junior Leader Fellowship awarded to C.G.C. (LCF/BQ/PR22/11920005), funded by the 'la Caixa' Foundation (ID 100010434), and the "Generación de Conocimiento 2022" project (TrophicStress, PID2022-141732NA-I00), funded by MICIU/AEI/10.13039/501100011033 and the EU FEDER programme. M.T.M. is supported by a predoctoral grant, "Formación de Profesorado Universitario" (FPU22/04290), funded by MICIU, as well as by the BiodivERsA and Water JPI 2020-2021 COFUND Call for Transnational Research Proposals through the ResPond project (BiodivRestore-614), funded by AEI and the European Union NextGenerationEU/PRTR (PCI2022-132973/AEI/10.13039/501100011033). J.B. and M.Á.-C. received funding from the project "*Los efectos del calentamiento en el funcionamiento fluvial: Una respuesta mediada a través de la biomasa*" (BIORESP; PID2023-150641OB-I00), funded by MICIU/AEI/10.13039/501100011033 and by FEDER, EU. A.L.'s work was supported by the INHOT (CNS2022-135690) and FLUPRINT (EUR2023-143456) projects, funded by MCIN/AEI/10.13039/501100011033 and the European Union NextGenerationEU/PRTR. R.C. and A.B. received funding from the Biodiversa+ project MOSTFUN (SNSF: 31BD30_216821). C.A. is supported by a predoctoral grant, "Formación de Personal Investigador" (PRE2020-094732), associated with the ClimaRiskinPond project (PID2019-104580GA-I00), funded by MCIN/AEI/10.13039/501100011033 and by the European Social Fund (ESF) under the motto "Investing in your future." E.F. was supported by a postdoctoral grant (POSTDOC-21-00225), funded by the Junta de Andalucía. The work of I.M.-S., M.M. and I.M. received funding from the project PID2020-115708RB-C21, funded by MCIN/AEI/10.13039/501100011033.

674 Additionally, I.M.-S. was supported by a Basque Government predoctoral grant (2023, J0D0Z-
675 T5967-AJZ8).

1276 Figures and Tables captions

1277 **Figure 1.** Locations of the study sites within the Iberian Peninsula and their context within Europe (red
1278 square).

1279 **Figure 2.** Boxplots showing the variation in (a) taxonomic richness, (b) functional richness (FRic), and
1280 (c) functional dispersion (FDis) across the study regions. Region abbreviations: CAN – Cantabrian
1281 Mountain Range, CAT – Catalonia, TAG – Mid Tagus, PT – North Portugal, SEG – Segura, DOU –
1282 South Douro, and AND – Andalusia.

1283 **Figure 3.** (a) Averaged and standardised model coefficients for the different fungal biodiversity facets,
1284 including taxonomic richness (Ric), functional richness (FRic), functional dispersion (FDis), and
1285 centroids of the first and second trait axes (Axis 1 and Axis 2). Red tones represent negative predictor
1286 effects, while blue tones indicate positive effects. (b) Mean explained variance of stressors and
1287 hydrology for the different fungal biodiversity facets, including taxonomic richness (Ric), functional
1288 richness (FRic), functional dispersion (FDis), and centroids of the first and second trait axes (Axis 1 and
1289 Axis 2). The random factor importance is not shown for simplicity (see further details in Table S7).

1290 **Figure 4.** Boxplots of: (a) decomposition rate (k_d) in the water column, (b) decomposition rate (k_d) in the
1291 streambed sediments, (c) fungal biomass in the water column, and (d) fungal biomass in the streambed

1292 sediments. The colours of the bars correspond to the regions (as shown in Figure 1). Region
1293 abbreviations are as follows: CAN, Cantabrian Mountain range; CAT, Catalonia; TAG, Mid Tagus; PT,
1294 North Portugal; SEG, Segura; DOU, South Douro; and AND, Andalusia.

1295 **Figure 5.** (a) Averaged and standardised model coefficients for the decomposition rate (k_d) and fungal
1296 biomass in the water column and streambed sediment. Red tones represent negative predictor effects,
1297 while blue tones indicate positive effects. (b) Mean explained variance of stressors and hydrology for
1298 the decomposition rate (k_d) and fungal biomass in both stream compartments. For simplicity, the
1299 importance of random factors is not shown here (see Table S7 for further details).

1300 **Table 1.** Fungal traits, their corresponding categories, and the references used for their definition. The
1301 table is adapted from Arias-Real et al. (2023) with additional references included.

1302 **Supplementary Material captions**

1303 **Figure S1.** Correlation between response variables.

1304 **Table S1.** Mean values and standard errors (mean \pm SE) for the environmental characteristics of the
1305 study regions. Region abbreviations are as follows: CAN – Cantabrian Mountain Range, CAT –
1306 Catalonia, TAG – Mid Tagus, PT – North Portugal, SEG – Segura, DOU – South Douro, and AND –
1307 Andalusia.

1308 **Table S2.** Mean values and standard errors (mean \pm SE) for the stressor variables in the study regions.
1309 Region abbreviations are as follows: CAN – Cantabrian Mountain Range, CAT – Catalonia, TAG – Mid
1310 Tagus, PT – North Portugal, SEG – Segura, DOU – South Douro, and AND – Andalusia.

1311 **Table S3.** Total number of species occurrences per region during the study period.

1312 **Table S4.** Means and standard error (mean \pm SE) of the taxonomic and functional metrics by region.
1313 Abbreviations are as follows: CAN, Cantabrian Mountain range; CAT, Catalonia; TAG, Mid Tagus; PT,
1314 North Portugal; SEG, Segura; DOU, South Douro; AND, Andalusia; Ric, taxonomic richness; FRic,
1315 Functional richness; FDis, functional dispersion; cent_ax1, centroids of the first trait axis; and, cent_ax2,
1316 centroids of the second trait axis.

1317 **Table S5.** Correlations between functional axes and fungal trait categories.

1318 **Table S6.** Summary of averaged coefficients for biodiversity and functional models.

1319 **Table S7.** Explained variance (R^2) for biodiversity and functional models.

1320 **Table S8.** Means and standard error (mean \pm SE) of the decomposition rates and fungal biomass accrual
1321 at each study site in both stream compartments (water column and streambed sediments).
1322 Abbreviations are as follows: CAN, Cantabrian mountain range; CAT, Catalonia; TAG, Mid Tagus; PT,
1323 North Portugal; SEG, Segura; DOU, South Douro; AND, Andalusia; BioM_sediment, fungal biomass in
1324 sediments; BioM_water-column, fungal biomass in the water column; kd_sediment, decomposition
1325 rates in sediments; kd_water-column, decomposition rates in the water column; ratio_k, ratio of
1326 decomposition rates; and ratio_bioM, ratio of fungal biomass.

1327 **Appendix 1.** Details on missing data imputation for stressors.

1328 **Appendix 2.** Details on performance of the models exploring functional and biodiversity responses to
1329 multiple stressors.

Supplementary material of “Combined effects of land-use- and climate-driven stressors on stream fungi and organic matter decomposition”

Authors: Aida Viza. Encarni Fenoy. Meritxell Abril. Mario Álvarez-Cabria. Rebeca Arias-Real. Christian Arnanz. José Barquín. Andi Bruder. Red Calore. Íñigo Donázar. Isabel Fernandes. Antonio J. García-Meseguer. Anna Lupon. Itxaso Martínez. Margarita Menéndez. Isabel Muñoz. Cláudia Pascoal. Marina Tomás-Martín and Cayetano Gutiérrez-Cánovas

Appendix 1: Details on missing data imputation for stressors.

Model performance sheet: Information on missing values and model specifications for each stressor.

Water temperature sheet: Model performance indicators for each stressor.

Remaining sheets: Predictive models for each response variable, including model estimates, standard errors, t-values, and p-values.

Abbreviations:

w_temp: Water temperature

DN: Dissolved nitrate

SRP: Dissolved reactive phosphorus

DOC: Dissolved organic carbon

DO.def: Dissolved oxygen deficit

w_temp: Water temperature

air_tmean: mean of air temperature

riparian_open: riparian canopy openness

lat: latitude

lon: longitude

Appendix 2. Details on performance of the models exploring functional and biodiversity responses to multiple stressors

Models selected to explore multiple stressor responses for each studied variable. Standardized model coefficients explained variance (r^2_m and r^2_c). AICc. ΔAIC and model weights are showed. We retained models meeting $\Delta AICc \leq 7$

Abbreviations:

sed_k: Decomposition rates of streambed sediments

sed_bioM: Fungal biomass of streambed sediments

wcol_k: Decomposition rates of the water column

wcol_bioM: Fungal biomass of the water column

ric: Taxonomic richness

FRic: Functional richness

FDis: Functional dispersion

Cent1: Centroid of Axis 1

Cent2: Centroid of Axis 2

w_temp: Water temperature

DN: Dissolved nitrate

SRP: Dissolved reactive phosphorus

DOC: Dissolved organic carbon

DO.def: Dissolved oxygen deficit

riparian_open: riparian canopy openness
